Abstract

The combination of hemorrhagic pneumonitis and rapidly progressive glomerulonephritis is a characteristic feature of Goodpasture's syndrome (GPS), an autoimmune disease resulting from the interaction of pathogenic anti-collagen type IV (C-IV) antibodies with alveolar and glomerular basement membranes. Lack of a suitable animal model for this fatal disease has hampered both a basic understanding of its etiology and the development of therapeutic strategies. We now report a novel model for GPS using mice deficient in a central regulatory receptor for immunoglobulin (Ig)G antibody expression and function, the type IIB Fc receptor for IgG (Fc γ RIIB). Mutant mice immunized with bovine C-IV reproducibly develop massive pulmonary hemorrhage with neutrophil and macrophage infiltration and crescentic glomerulonephritis. The distinctive linear, ribbon-like deposition of IgG immune complex seen in GPS was observed along the glomerular and tubulointerstitial membranes of diseased animals. These results highlight the role of Fc γ RIIB in maintaining tolerance and suggest that it may play a role in the pathogenesis of human GPS.

Key words: Goodpasture's syndrome • type IV collagen • Fc receptor • autoimmunity • alveolar/glomerular basement membrane

Introduction

Patients with Goodpasture's syndrome (GPS) display a characteristic rapid and progressive glomerulonephritis and hemorrhagic pneumonitis with often fatal results (1–3). The presence of anti-collagen type IV (C-IV) antibodies and the characteristic ribbon pattern of immune complex deposition along the basement membranes of both lung and glomeruli has led to a proposed pathogenic model for this disease (4–6). Autoantibodies to common components of the basement membranes of these two organs develop, notably to the α 3 domain of C-IV, are deposited (7), and trigger effector cell activation and inflammatory sequelae. The mechanism(s) that result in the loss of tolerance and

the development of autoantibodies to C-IV are unknown. Investigations into the proposed pathogenesis of this disease and development of therapeutic strategies have been hampered by the lack of a suitable animal model. Attempts to develop such a model for GPS by immunizing sheep (8) or rats (9, 10) with homologous or heterologous glomerular basement membrane preparations have resulted in only partial success. For example, Abate et al. (10) induced glomerulonephritis and hemorrhagic pneumonitis in Wistar-Kyoto rats by immunization with the α 3 chain of C-IV, but the observed lesions were only marginal. Similarly, injecting anti-glomerular basement membrane antibody into mice or their immunization with recombinant protein for the NC1 domain of the α 3 chain of C-IV resulted in little or only marginal alveolar hemorrhage, in spite of the development of glomerular disease (11). These studies support the conclusion that immunization with C-IV alone is insuffi-

cient to trigger the full spectrum of GPS, thus pointing to the contribution of additional susceptibility factors necessary to the development of full-blown disease.

We have previously shown that Fc γ RIIB-deficient (Fc γ RIIB^{-/-}) mice of the H-2^b haplotype are susceptible to type II collagen-induced arthritis (12), a model for rheumatoid arthritis in humans, which previously could only be induced in susceptible rodents of particular MHC haplotypes, specifically H-2^q or H-2^r in mice. The etiology of the arthritis seen in these Fc γ RIIB^{-/-} animals could be attributed to the enhanced humoral immune response to type II collagen and augmented proinflammatory mediator release by effector cells such as macrophages (12). The inhibitory Fc receptor for IgG immune complexes, Fc γ RIIB, plays a central role in both the afferent and efferent limbs of the immune response, shaping the antibody repertoire, maintaining peripheral tolerance, and setting thresholds for effector cell activation. Animals deficient in this receptor have generalized enhanced antibody responses (13) and heightened inflammation in all antibody-mediated classes of hypersensitivity reactions (12, 14). These observations prompted us to test whether Fc γ RIIB may regulate responses to C-IV and be a critical factor in GPS development. Our data indicate that immunization of Fc γ RIIB^{-/-} animals with C-IV results in autoimmunity and culminates in GPS-like disease, suggesting a role for the Fc γ RIIB regulatory pathway in the etiology of this autoimmune disease.

Materials and Methods

Animals. Fc γ RIIB^{-/-} mice were generated in the 129/SvJ (H-2^b) and C57BL/6 (B6, H-2^b) hybrid background as described previously (13). FcR γ ^{-/-} mice (15) were backcrossed to B6 mice over six generations. These mice and their wild-type counterparts (129/B6 hybrids and B6 mice for Fc γ RIIB^{-/-} and FcR γ ^{-/-}, respectively) were kept and bred in the Animal Unit of The Institute of Development, Aging and Cancer (Tohoku University, Japan), an environmentally controlled and specific pathogen-free facility. B6 mice were obtained from Charles River Labs. Japan, Inc. All experiments were performed on 8-wk-old male and female mice.

C-IV Immunization. Bovine C-IV (Cellmatrix IV[®]) was obtained from Nitta Gellatin, Inc. The C-IV solution (3.0 mg/ml in 1 mM HCl, pH 3.0) was neutralized by adding 1 mM NaOH (final concentration) before emulsifying with Freund's adjuvant. Mice were immunized at the tail base with 150 μ g of C-IV emulsified in CFA containing *Mycobacterium tuberculosis* strain H₃₇Rv (Wako Pure Chemical Industries, Ltd.) and boosted at the same location with 150 μ g of C-IV plus IFA (Wako Pure Chemical Industries, Ltd.) 2, 4, and 6 wk later. The mice were killed 56 d later and processed for histopathological examinations.

Assay for Detection of Serum Anti-C-IV Antibodies. Blood was collected from the subocular plexus of mice into microcentrifuge tubes containing EDTA on ice, and plasma was prepared. Serum antibody titers were measured by ELISA. Antibodies to bovine C-IV were detected in a 96-well microplate assay (Falcon; Becton Dickinson Labware) in which wells were coated with 50 μ l/well of a 20 μ g/ml solution of bovine C-IV in PBS at 4°C for overnight, washed three times with PBS containing 0.05% Tween 20 and 0.1% BSA, and then blocked with 250 μ l/well of

PBS containing 0.2% BSA at 4°C for overnight. Antibodies to mouse C-IV were detected by the use of the BICOAT[®] cellware mouse C-IV 96-well plate assay (Becton Dickinson Labware). The diluted serum (1:2,500–5,000) was added at 50 μ l/well and allowed to react overnight at 4°C. The wells were washed three times with PBS containing 0.05% Tween 20, incubated with 50 μ l of a 1:200 dilution of goat anti-mouse IgG1, IgG2a, IgG2b, IgM, or IgA coupled to horseradish peroxidase (Sigma Chemical Co.) at 4°C for 2 h, washed three times with PBS containing 0.05% Tween 20, and developed at room temperature for 30 min with 0.1 ml of TrueBlue Peroxidase Substrate (Kirkegaard & Perry Labs.). The OD at 450 nm was read using a Biolumin960 Microplate Reader (Molecular Dynamics Japan, Inc.).

Evaluation of Renal Functions. Serum samples at 56 d were inspected for blood urea nitrogen (BUN) and serum creatinine (Cr) levels by the urease GLDH-UV method and ELISA using a TOSHIBA TBA-80FR. Proteinuria was monitored by the tetrabromophenol blue reaction assay using the Micro AUTION MA-4260 (Kyoto Daiichi Kagaku Co.).

Histological Study and Immunohistochemistry. Mice were killed by cervical dislocation at day 56. Their lungs and kidneys were removed and fixed in 10% (vol/vol) neutral buffered formalin, followed by embedding in paraffin. The lung specimens were sectioned at 5 μ m and stained with hematoxylin and eosin or periodic acid-Schiff (PAS). The kidney sections were stained with PAS. Alternatively, formalin-fixed and paraffin-embedded lung and kidney section (5 μ m) were deparaffinized in xylene and rehydrated through graded ethanols. After washing with distilled water, sections were incubated in PBS containing STUF (Serotec Target Unmasking Fluid; Serotec Ltd.) for 10 min at 90°C and washed again three times with PBS. Sections were then incubated for 30 min at room temperature with affinity-purified, fluorescein-conjugated goat F(ab')₂ fragments (H + L chain) anti-mouse IgG, IgM, or C3 (Zymed Labs., Inc.). After washing three times in PBS, slides were mounted and examined with an Olympus BX50 microscope equipped with epifluorescence using an Olympus BH2-RFL-T3 mercury lamp and appropriate optics. Crescentic glomerulonephritis were counted in at least 50 glomeruli randomly selected in a histologic section from each mouse.

Cell Separation and Transfer Experiments. Fc γ RIIB^{-/-} mice were immunized with C-IV as described above. Splenocyte suspensions from the diseased Fc γ RIIB^{-/-} mice were prepared at day 56, treated with 0.144 M NH₄Cl for 1 min for depletion of erythrocytes, and then transferred intravenously (2 \times 10⁷ cells per mouse) to either Fc γ RIIB^{-/-} or wild-type naive mice. Alternatively, splenocytes were separated to B220⁺ and B220⁻ cells by magnetic sorting (B220 MACS[®] microbeads; Miltenyi Biotec) before cell transfer. These recipient mice were then boosted 7 d later with 150 μ g of C-IV in IFA and killed 21 d later.

Results and Discussion

Fc γ RIIB^{-/-} mice, immunized with bovine C-IV in CFA and boosted at 2, 4, and 6 wk with antigen in IFA, developed a GPS-like disease with pulmonary hemorrhage (Fig. 1) and glomerulonephritis (Fig. 2). Nearly all immunized Fc γ RIIB^{-/-} mice developed pulmonary hemorrhage, whereas none of the wild-type controls displayed evidence of disease (Table I; 22 of 24 [92%] versus 0 of 14 [0%], respectively; *P* < 0.001). The appearance of the diseased lungs (Fig. 1 A) revealed extensive hemorrhage diffusely scattered throughout the organ, in sharp contrast to

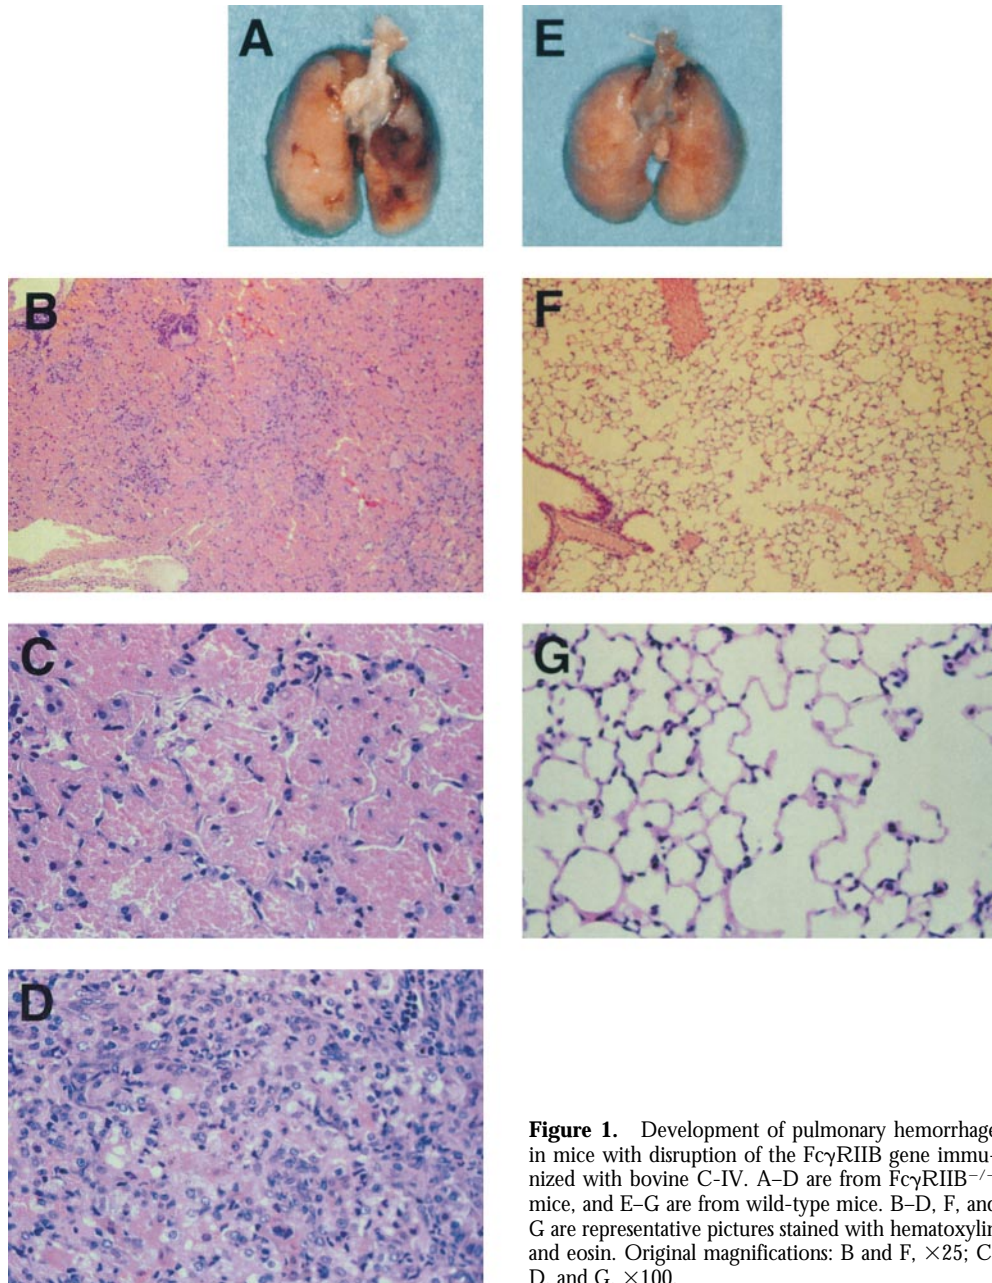

Figure 1. Development of pulmonary hemorrhage in mice with disruption of the $Fc\gamma RIIB^{-/-}$ mice, and E-G are from wild-type mice. B-D, F, and G are representative pictures stained with hematoxylin and eosin. Original magnifications: B and F, $\times 25$; C, D, and G, $\times 100$.

the results reported in previous attempts to induce GPS in rats and mice (9–11), in which only regional hemorrhagic patches were observed. Histopathological examinations of a diseased lung indicate massive hemorrhage with infiltrating neutrophils and macrophages (Fig. 1, B–D), whereas lung samples from wild-type mice were normal (Fig. 1, F and G). The diseased animals displayed bilateral alveolar hemorrhage (data not shown) as well as alveolar capillaritis with extensive infiltration of neutrophils and macrophages (Fig. 1 D). During this experiment, five of the immunized $Fc\gamma RIIB^{-/-}$ mice died of tracheal obstruction caused by hemoptysis (Table I).

Histopathological examination of the kidneys in immunized $Fc\gamma RIIB^{-/-}$ animals revealed typical crescentic glomerulonephritis and tubulointerstitial nephritis, with infiltration of neutrophils and multinuclear giant cells and hyaline droplet degeneration of the tubules in nearly all mice tested (22 of 24 mice tested [92%]; Fig. 2, A and B), whereas kidneys from wild-type mice did not show any pathological changes (Fig. 2, C and D). Immunized $Fc\gamma RIIB^{-/-}$ mice showed higher BUN and serum Cr levels than controls (Table I), further confirming the compromised renal function. In addition, all diseased animals showed proteinuria, with mean protein levels of 533 mg/dl in the urine (data not shown). Immunohistochemical staining of glomeruli from immunized $Fc\gamma RIIB^{-/-}$ animals with FITC-labeled anti-mouse IgG demonstrated linear depositions of IgG immune complexes along the glomerular membrane (Fig. 3 A), in a

erulonephritis and tubulointerstitial nephritis, with infiltration of neutrophils and multinuclear giant cells and hyaline droplet degeneration of the tubules in nearly all mice tested (22 of 24 mice tested [92%]; Fig. 2, A and B), whereas kidneys from wild-type mice did not show any pathological changes (Fig. 2, C and D). Immunized $Fc\gamma RIIB^{-/-}$ mice showed higher BUN and serum Cr levels than controls (Table I), further confirming the compromised renal function. In addition, all diseased animals showed proteinuria, with mean protein levels of 533 mg/dl in the urine (data not shown). Immunohistochemical staining of glomeruli from immunized $Fc\gamma RIIB^{-/-}$ animals with FITC-labeled anti-mouse IgG demonstrated linear depositions of IgG immune complexes along the glomerular membrane (Fig. 3 A), in a

Figure 2. Development of glomerular changes in mice with disruption of Fc γ RIIB. Histological findings of the kidney stained with PAS after immunization with C-IV in Fc γ RIIB $^{-/-}$ (A and B) and wild-type mice (C and D). Original magnifications: A and C, $\times 25$; B and D, $\times 100$. Wild-type mice yielded no distinct findings, but Fc γ RIIB $^{-/-}$ mice showed crescentic glomerulonephritis.

characteristic ribbon-like pattern, and tubulointerstitial membrane (Fig. 3 B). In contrast, the deposition of IgG was hardly detectable in immunized wild-type mice (Fig. 3 C). Neither IgM nor C3 deposition was detected along the glomerular basement membranes in the diseased mice (data not shown).

Histological examination of eye, heart, and liver samples taken from immunized Fc γ RIIB $^{-/-}$ animals at necropsy did not reveal any evidence of inflammatory disease (data not shown), confirming that the disease process evident in the susceptible animals was not the result of a diffuse systemic inflammatory process. However, the possibility that subclinical autoimmune infiltration of other organs (e.g., gut, central nervous system) occurs has not been ruled out. In the

absence of bovine C-IV immunization, Fc γ RIIB $^{-/-}$ mice do not develop any abnormalities in pulmonary and renal function (data not shown), indicating the necessity of an inductive stimulus to trigger disease in this susceptible background. The identification of Fc γ RIIB as a susceptibility factor in GPS and the ability to induce disease upon immunization with bovine C-IV offers the opportunity to investigate other presumptive triggers in the RIIB $^{-/-}$ mouse, such as toxic oxygen, hydrocarbons, or viruses, all of which have been suggested as possible inducers of human GPS (16).

The pulmonary and renal lesions of GPS are attributed to anti-glomerular basement membrane antibodies, which bind to common antigenic sites in the lung and kidney and activate inflammatory effector responses. Consistent with this

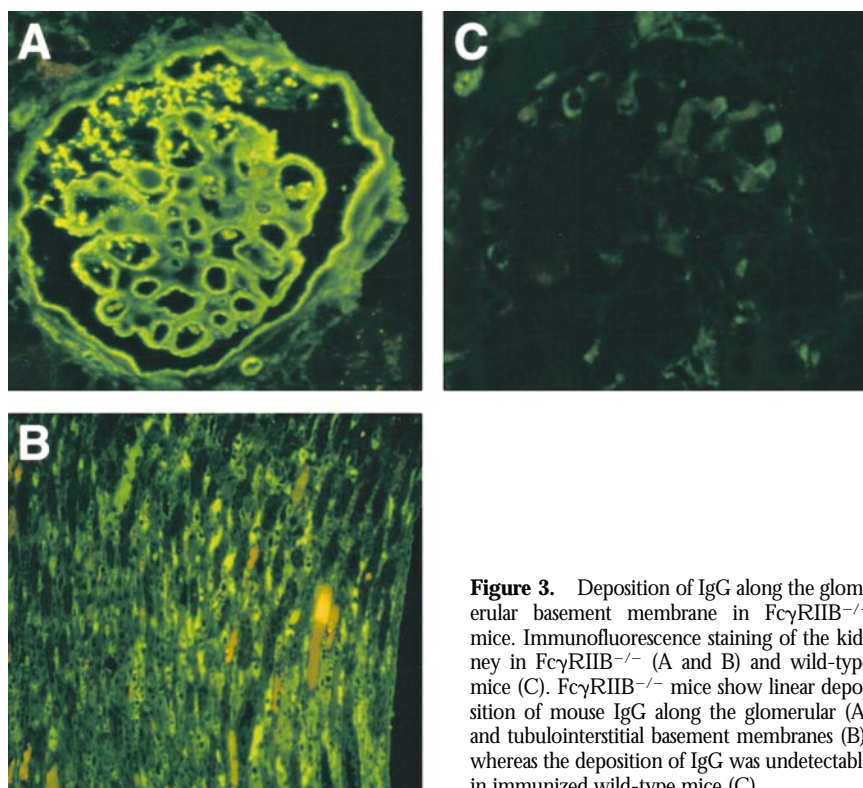

Figure 3. Deposition of IgG along the glomerular basement membrane in $Fc\gamma RIIB^{-/-}$ mice. Immunofluorescence staining of the kidney in $Fc\gamma RIIB^{-/-}$ (A and B) and wild-type mice (C). $Fc\gamma RIIB^{-/-}$ mice show linear deposition of mouse IgG along the glomerular (A) and tubulointerstitial basement membranes (B), whereas the deposition of IgG was undetectable in immunized wild-type mice (C).

pathogenic model, the antibody response of $Fc\gamma RIIB^{-/-}$ mice to bovine C-IV immunization is enhanced relative to wild-type controls, with elevated titers of anti-bovine C-IV IgG1, IgG2a, IgG2b, and IgM antibodies observed (Fig. 4, A–D). Anti-C-IV IgA was not detected during the 8-wk

experimental period of this study (Fig. 4 E), despite the recent description of IgA κ GPS in humans (17). Importantly, $Fc\gamma RIIB^{-/-}$ mice, but not wild-type or $FcR\gamma^{-/-}$ mice, showed elevated autoantibody responses to mouse C-IV (Fig. 4, F–H), suggesting that murine GPS depends on the

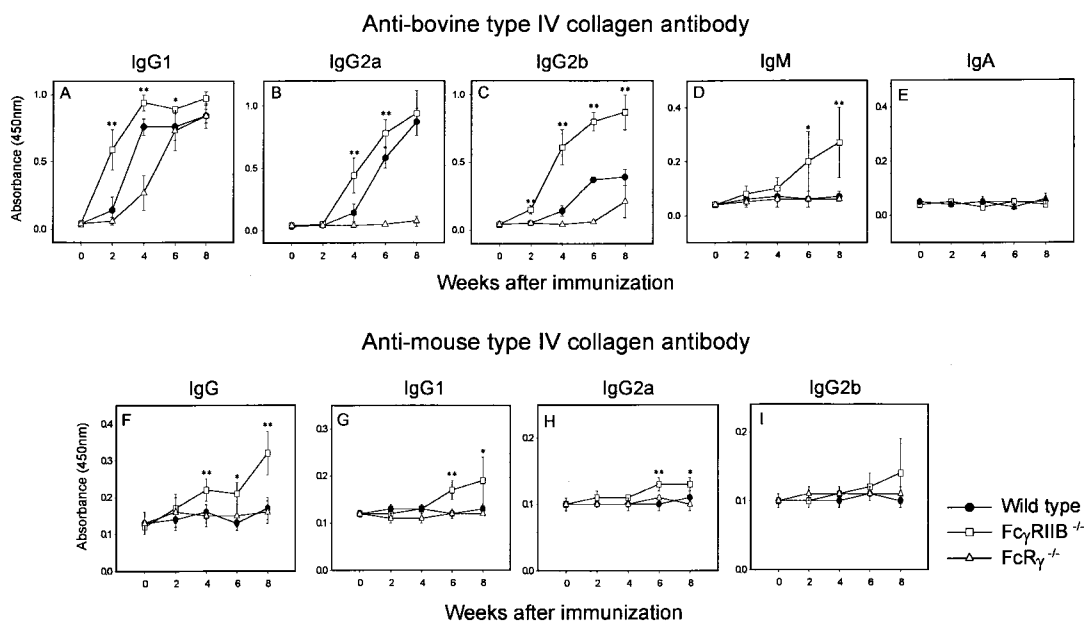

Figure 4. Concentration of anti-bovine C-IV and anti-mouse C-IV antibodies in sera from mice immunized with bovine C-IV. Anti-bovine C-IV antibody levels of IgG1, IgG2a, IgG2b, IgM, and IgA subclasses (A–E) and anti-mouse C-IV levels of total IgG, IgG1, IgG2a, and IgG2b (F–I) in wild-type (●), $Fc\gamma RIIB^{-/-}$ (□), and $FcR\gamma^{-/-}$ (△) mice. Wild-type mice were used as controls for $Fc\gamma RIIB^{-/-}$ mice as described in Materials and Methods. Each point represents the mean \pm SD. autoantibody production in this susceptible background. Although this enhanced antibody response may account for the GPS disease that develops in these animals, it is likely that contributions from enhanced effector cell responses to deposited anti-C-IV autoantibodies are a significant factor in the development of disease, as described in the enhanced macrophage responses in immune complex-mediated alveolitis (18) and in collagen-induced arthritis (12). In support of this notion, the alveolar and glomerular diseases could be transferred only to Fc γ RIIB^{-/-} animals (five of nine mice tested) but not to wild-type mice (zero of eight mice tested) by injecting C-IV-sensitized splenocytes from Fc γ RIIB^{-/-} mice into nonsensitized animals. Disease could not be transferred by injecting either B220⁺ or B220⁻ splenocytes from C-IV-sensitized Fc γ RIIB^{-/-} mice into nonsensitized RIIB^{-/-} mice (zero of five mice tested), suggesting the additional requirement of sensitized T and B cell cooperation in disease development (data not shown).

In this study, several differences have been observed between this animal model and human GPS. First, we found the lack of C3 deposition in the kidneys (data not shown) and the absence of anti-C-IV antibodies of the IgA isotype (Fig. 4 E) as well as the low mortality rate (Table I) in this model. In human GPS, the deposition of IgM or C3 was detected along the glomerular basement membranes in some patients (19), and the deposition of IgA was reported in one patient (17). It remains to be investigated which factor(s) can induce IgM, C3, or IgA deposition in the murine kidneys in the present model. Second, untreated GPS in humans carries a much higher mortality rate; persons with the full-blown syndrome die within a few months (19), compared with the mortality rate of 21% at day 56 in the present model (Table I), although the clinical severity of lung hemorrhage is almost the same for diseased animals and human GPS (Fig. 1). The reason for the differing lifespans of diseased mice and humans might partially depend on the difference of the resistance to hypoxia caused by alveolar hemorrhage. In our estimation, the surviving animals at day 56 could also be alive at day 70. Additional immunizations of these surviving animals with C-IV would increase their mortality rate.

The observation that Fc γ RIIB deficiency creates a permissive immunological environment for the development of anti-C-IV autoantibodies offers further support for a role for this receptor in the mechanism of maintaining tolerance. Fc γ RIIB inhibits activation responses triggered by cross-linking of the B cell antigen receptor (BCR), establishing cellular thresholds for lymphocyte stimulation (20, 21). In addition, Fc γ RIIB is capable of triggering apoptosis when it is cross-linked in the absence of the BCR (22). The activities associated with Fc γ RIIB are manifested in the peripheral lymphoid compartment, during the process of affinity maturation and memory generation in the germinal center (reference 22 and Tew, J., T. Manser, and J.V. Ravetch, manuscript submitted for publication). Fc γ RIIB expression on B cells is proposed to prevent the activation, proliferation, and expansion of low-affinity autoreactive cells in the periphery. Deficiency in Fc γ RIIB function removes this checkpoint and thereby contributes to the development of autoimmu-

nity. The data presented here on the role of Fc γ RIIB in GPS suggest that alterations in the function or expression of the Fc γ RIIB gene could be a susceptibility factor in the pathogenesis of the human disease. This novel model for GPS offers the opportunity to dissect the etiological mechanisms of disease development and the identification of agents that trigger autoantibody production in a susceptible background, thereby offering new insights into the development of new therapeutic approaches for the treatment of this disease.

We are grateful to Dr. Katsuhiko Nakata, Muneo Hamada, and Miwa Yamamoto (Nara Research and Development Center, Santen Pharmaceutical Co., Nara, Japan) for their pathological examinations of eyes, Dr. Masahito Ebina (Department of Respiratory Oncology and Molecular Medicine, Institute of Development, Aging and Cancer, Tohoku University, Japan) for his helpful discussions, and Naomi Takagi for secretarial support.
