Department of Anesthesiology, Washington University School of Medicine, St. Louis, MO 63110

N termini of auxiliary  $\beta$  subunits that produce inactivation of large-conductance  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  (BK) channels reach their pore-blocking position by first passing through side portals into an antechamber separating the BK pore module and the large C-terminal cytosolic domain. Previous work indicated that the  $\beta 2$  subunit inactivation domain is protected from digestion by trypsin when bound in the inactivated conformation. Other results suggest that, even when channels are closed, an inactivation domain can also be protected from digestion by trypsin when bound within the antechamber. Here, we provide additional tests of this model and examine its applicability to other  $\beta$  subunit N termini. First, we show that specific mutations in the  $\beta 2$  inactivation segment can speed up digestion by trypsin under closed-channel conditions, supporting the idea that the  $\beta 2$  N terminus is protected by binding within the antechamber. Second, we show that cytosolic channel blockers distinguish between protection mediated by inactivation and protection under closed-channel conditions, implicating two distinct sites of protection. Together, these results confirm the idea that  $\beta 2$  N termini can occupy the BK channel antechamber by interaction at some site distinct from the BK central cavity. In contrast, the  $\beta 3a$  N terminus is digested over 10-fold more quickly than the  $\beta 2$  N terminus. Analysis of factors that contribute to differences in digestion rates suggests that binding of an N terminus within the antechamber constrains the trypsin accessibility of digestible basic residues, even when such residues are positioned outside the antechamber. Our analysis indicates that up to two N termini may simultaneously be protected from digestion. These results indicate that inactivation domains have sites of binding in addition to those directly involved in inactivation.

## INTRODUCTION

Rapid inactivation of large-conductance  $\text{Ca}^{2+}$ -activated  $\text{K}^+$  (BK) channels is mediated by N-terminal cytosolic hydrophobic peptide segments of auxiliary  $\beta$  subunits (Wallner et al., 1999; Xia et al., 1999; Uebele et al., 2000; Xia et al., 2000, 2003). Such peptide segments are thought to obstruct ion flux by binding within the BK channel central cavity. To access this binding site,  $\beta$  subunit N termini must approach the axis of the permeation pathway laterally (Fig. 1 A), passing through the so-called side portals (Gulbis et al., 2000; Kobertz et al., 2000) that separate the membrane-embedded pore module and the large cytosolic structure involved in ligand recognition (Zhang et al., 2006). BK  $\beta$  subunit N termini contain basic residues that can be attacked by trypsin, thereby removing  $\beta$  subunit-mediated inactivation. Using quantitative measurement of trypsin-mediated removal of inactivation, it has been shown that the space between the pore domain and cytosolic domain defines a volume in which the  $\beta 2$  N terminus is protected from digestion by trypsin, and this protected volume has been termed an antechamber (Zhang et al., 2006). The properties of removal by trypsin of

$\beta 2$ -mediated inactivation are consistent with a model in which, even under conditions in which channels are closed, individual N termini occupy the antechamber for an appreciable fraction of time, thereby conferring some protection against digestion by trypsin (Fig. 1 B). Thus, a determinant of the time course of digestion by trypsin reflects not just the accessibility of the basic residues, but also the fraction of time a  $\beta 2$  N terminus resides within the protected antechamber.

The primary evidence supporting the protected antechamber idea arose from the observation that, under conditions that favor inactivation, digestion of the  $\beta 2$  N terminus was markedly slowed. The critical motif necessary for  $\beta 2$  subunit-mediated inactivation is a triplet of hydrophobic residues, FIW, that immediately follows the N-terminal methionine (Xia et al., 2003). Therefore, the trypsin susceptibility of a series of artificial N termini was examined for which basic residues were positioned at different distances from the FIW triplet. These experiments revealed that, when in an inactivated position, basic residues were protected from digestion only when they were positioned within 12 residues of the N-terminal FIW (Zhang et al., 2006). Interestingly,

this 12-residue length also corresponds to the minimal linker length between the  $\beta 2$  subunit transmembrane segment 1 (TM1) and the FIW epitope that is required for an N terminus to be inactivation competent (Xia et al., 2003). Together, these results suggest that, over the length spanned by the 12-residue segment between TM1 and the binding site of the FIW motif within the central cavity, basic residues are protected from digestion by trypsin. However, for digestion of N termini when channels are closed, the time course of trypsin-mediated digestion of  $\beta 2$  N termini was described by a power term,  $n$ , of  $\sim 2.0$ – $2.5$  (see Eq. 1 in Materials and methods). For the simple case in which all N termini are equally digestible by trypsin, the digestion process should exhibit a power term of 4. To explain a power term of  $n = 2.0$ – $2.5$ , it was therefore proposed that, with channels mainly closed, not all N termini are equally accessible to digestion by trypsin, perhaps because some N termini are transiently protected from digestion by occupancy of an antechamber. To account for the ob-

servations a model was proposed (Fig. 2 A, Scheme 1) in which, even for closed channels, only one of the four N termini can occupy the protected volume at a time.

Although the antechamber occupancy model accounts well for the key features of the earlier data, the idea that some N termini can be protected from digestion in closed channels depends largely on the observation of a power term  $< 4$ . An untested prediction of the model is that, if the occupancy time in the antechamber could be reduced, the overall digestion time course should be two- to fivefold faster with an associated increase in the value of  $n$  (Zhang et al., 2006). Here, we provide additional support for this idea through three approaches. First, to assess whether specific determinants of the  $\beta 2$  N terminus are responsible for protection when channels are closed, we examined mutated  $\beta$  subunit N termini. Second, to assess whether pore occupancy and antechamber occupancy involve distinct binding events, we examined the ability of cytosolic quaternary blockers to speed up the digestion time course. Third, to assess whether there

are  $\beta$  subunit-specific determinants of fractional occupancy within the antechamber, we examined the trypsin sensitivity of other  $\beta$  subunit N termini. Overall, the results provide additional validation for the idea that binding of an N terminus within a protected antechamber provides protection against digestion by trypsin. We also address the issue of whether such protection arises because basic residues are physically hidden from attack by trypsin within the antechamber or whether binding of the N terminus places structural constraints on the basic residues, thereby reducing attack by trypsin.

## MATERIALS AND METHODS

### Oocyte Removal and Culture

Stage IV *Xenopus laevis* oocytes were injected with cRNA as described previously (Xia et al., 1999, 2002). mSlo1  $\alpha$  and  $\beta$  subunit cRNA were prepared at  $\sim 1 \mu\text{g}/\mu\text{l}$ . Typically, the  $\alpha$  cRNA was initially diluted to 1:20 by volume, and then the injection solution was prepared at cRNA ratios of 1:2 ( $\alpha/\beta$ ). For some constructs, the relative amount of  $\beta$  subunit cRNA was increased to ensure full stoichiometric assembly of  $\alpha$  and  $\beta$  subunits. Currents were typically recorded within 3–5 d after cRNA injection.

### Constructs and Mutations

The mSlo1 construct (GenBank accession no. NP\_034740) was originally obtained from L. Salkoff (Washington University School of Medicine, St. Louis, MO) and is identical to that in earlier work (Xia et al., 1999, 2002). The wild-type human  $\beta 2$  subunit (GenBank accession no. NP\_852006) was as described previously (Xia et al., 1999). Preparation of new h $\beta 2$  N-terminal mutations followed previously published procedures (Xia et al., 2003). The mouse  $\beta 3a$  subunit was assembled from expressed sequence tags based on exons defined in the mouse genome (Zeng et al., 2008). Table I lists N-terminal sequences for many constructs generated for this project along with the wild-type human  $\beta 2$ , mouse  $\beta 3a$ , and mouse and human  $\beta 3b$  N termini.

### Electrophysiology

Currents were recorded from inside-out patches (Hamill et al., 1981) using an Axopatch 200 amplifier (MDS Analytical Technologies) with stimulation protocols and data acquisition under control of the Clampex program (MDS Analytical Technologies). Recording pipettes used borosilicate capillary tubes, had resistances of 1–3 M $\Omega$ 's after fire polishing, and were coated with Sylgard 184 (Dow Corning). During seal formation, oocytes were maintained in frog ringer (in mM: 115 NaCl, 2.5 KCl, 1.8 CaCl<sub>2</sub>, and 10 HEPES, pH 7.4). The pipette/extracellular solution was as follows (in mM): 140 K-methanesulfonate, 20 KOH, 10 HEPES, and 2 MgCl<sub>2</sub>, pH 7.0. The solution used for bathing the cytosolic membrane contained 140 mM potassium methanesulfonate, 20 mM KOH, 10 mM HEPES(H<sup>+</sup>), and one of the following: 5 mM EGTA (for nominally 0 Ca<sup>2+</sup>) or 5 mM HEDTA (with Ca<sup>2+</sup> added to make 10  $\mu\text{M}$  free Ca<sup>2+</sup>). A Ca<sup>2+</sup>-sensitive electrode was used to calibrate the 10  $\mu\text{M}$  solution by comparing it to commercial Ca<sup>2+</sup> solutions (World Precision Instruments). Solutions were applied to patches through a continuously flowing stream with a multibarrel local application system. The experimental temperature was  $\sim 22$ – $25^\circ\text{C}$ . *N*-(4-[benzoyl]benzyl)-*N,N,N*-tributylammonium bromide (bbTBA) was obtained from Spectra Group Limited. Other chemicals were from Sigma-Aldrich.

### Trypsin Application Methods

Trypsin was from porcine pancreas (chymotrypsin, <1 unit/mg protein; type IX-S; Sigma-Aldrich). Previous work established that

digestion of  $\beta 2$  N termini by trypsin reflects an action at basic residues, indicative that contamination by other enzymes is minimal (Zhang et al., 2006). A  $\beta 2$  N terminus in which all basic residues were neutralized to Q ( $\beta 2$ -10Q) exhibits no digestion by trypsin over the time course of these experiments (Zhang et al., 2006).

The trypsin application procedures are as described previously (Zhang et al., 2006). In brief, peak and steady-state BK current activated by 10  $\mu\text{M}$  Ca<sup>2+</sup> was monitored by 200-ms test steps to +140 mV after a 30–50-ms preconditioning step to  $-140$  mV. Between test steps, trypsin was applied for timed intervals while the patch was maintained in conditions that bias the channel-gating equilibrium. The three test conditions used were: (1) 0 Ca<sup>2+</sup>, 0 mV (channels are closed); (2) 0 Ca<sup>2+</sup>,  $-80$  mV (channels are closed; the more negative holding potential was necessary for some mutated constructs); and (3) 10  $\mu\text{M}$  Ca<sup>2+</sup>, 0 mV (channels are mostly inactivated). Although trypsin was applied for precisely timed intervals, the exact time course of wash-in and washout of trypsin from the patch is unknown. Care was taken to ensure that each patch was maintained in the particular test condition (voltage and Ca<sup>2+</sup>) for at least 15 s before and after trypsin application, before test steps to monitor BK status were initiated. When effects of quaternary ammonium blockers on digestion time course were evaluated, blockers were applied at the beginning and end of a particular test condition for a period that preceded the onset of trypsin application and persisted after washout of trypsin. This ensured that blocker occupancy was at steady state both before and after trypsin application.

### Data Analysis

Current waveforms were analyzed either with Clampfit (MDS Analytical Technologies) or with programs written in this laboratory. The time course of removal of inactivation was fit with the following function (Zhang et al., 2006):

$$I(t)/I_{\max} = (1 - \exp(-t/\tau_d))^n, \quad (1)$$

where  $I_{\max}$  is the maximal peak outward current observed after removal of inactivation,  $\tau_d$  is the time constant of the process, and  $n$  is a power factor. This function postulates that inactivation arises from the binding of a single inactivation domain, but that  $n$  domains must be cleaved by trypsin to remove inactivation (Ding et al., 1998; Wang et al., 2002; Zhang et al., 2006). The application of this equation has been considered in more detail previously (Zhang et al., 2006). In some constructs, studied under inactivating conditions, inactivation was incompletely removed even at the end of  $\sim 15$  cumulative minutes of trypsin digestion. In such cases, the peak current measured during test steps was not a good measure of  $I_{\max}$  and, thus, the empirically observed  $I_{\max}$  in an individual experiment would result in an inappropriately rapid digestion time course. In such cases, the true  $I_{\max}$  was therefore estimated by the fold increase in peak current defined for a set of patches from a given construct studied when channels are largely closed.

### Modeling of Trypsin-mediated Removal of Inactivation

As before (Zhang et al., 2006), the trypsin-mediated removal of inactivation was modeled with the macroscopic simulation capabilities of the QUB software suite ([http://www.qub.buffalo.edu/wiki/index.php/Main\\_Page](http://www.qub.buffalo.edu/wiki/index.php/Main_Page)). Gating parameters used here were as described (Zhang et al., 2006) and are based on previous studies of BK activation and inactivation. Here, we extend the simulations to examine the consequences of changes in the affinity of binding within the antechamber and binding within the central cavity. Furthermore, we consider a two-site protection model.

In earlier work, we determined predicted digestion time constants,  $\tau_d$ , and power terms,  $n$ , for a one-site protection model as a function of fractional occupancy of that site (Fig. 6 E from

**Figure 1.** Cartoons summarizing the idea of antechamber occupancy and lateral access of  $\beta 2$  N termini to the BK channel pore. (A) The pathway for access of the  $\beta 2$  N-terminal inactivation domain to the BK channel central cavity is schematized. N termini must enter the central cavity by passing through the side portals separating the BK channel pore domain from the cytosolic domains involved in  $\text{Ca}^{2+}$  binding. The lateral distance from the center of the pore to the position where the N terminal attaches to the  $\beta 2$  subunit TM1 domain is estimated to be  $\sim 45\text{--}60$  Å (Zhang et al., 2006). Each ball in the schematized N terminus represents an amino acid, with red indicating basic residues and blue indicating the FIW hydrophobic triplet essential for inactivation. (B) Cartoons schematically summarize proposed configurations of  $\beta 2$  N termini during gating and inactivation. Each channel contains four  $\beta 2$  subunits (containing a triplet of hydrophobic residues [blue] at the N terminus and two digestible basic residues, R8 and R19 [red]), each of which can potentially enter the channel antechamber (equilibrium,  $B_a$ ) through side portals. The central pore is indicated by the shaded, inner circle (smaller, closed channel; larger, open channel). In this scheme, only one N terminus can occupy the antechamber at a time. Channels open in accordance with equilibrium constant  $L$ . Open channels with a  $\beta 2$  N terminus in the antechamber may also inactivate (equilibrium constant,  $B_i$ ).

Zhang et al., 2006). We have now determined that the calculation of fractional occupancies in the earlier plot contained an error. However, the relationship between fractional prolongation of  $\tau_d$  and  $n$  at different occupancies was correct and is identical to that reported here (Fig. 12, B and C). This error does not alter the conclusion that increases in fractional occupancy at the site of protection slow  $\tau_d$  and reduce  $n$ .

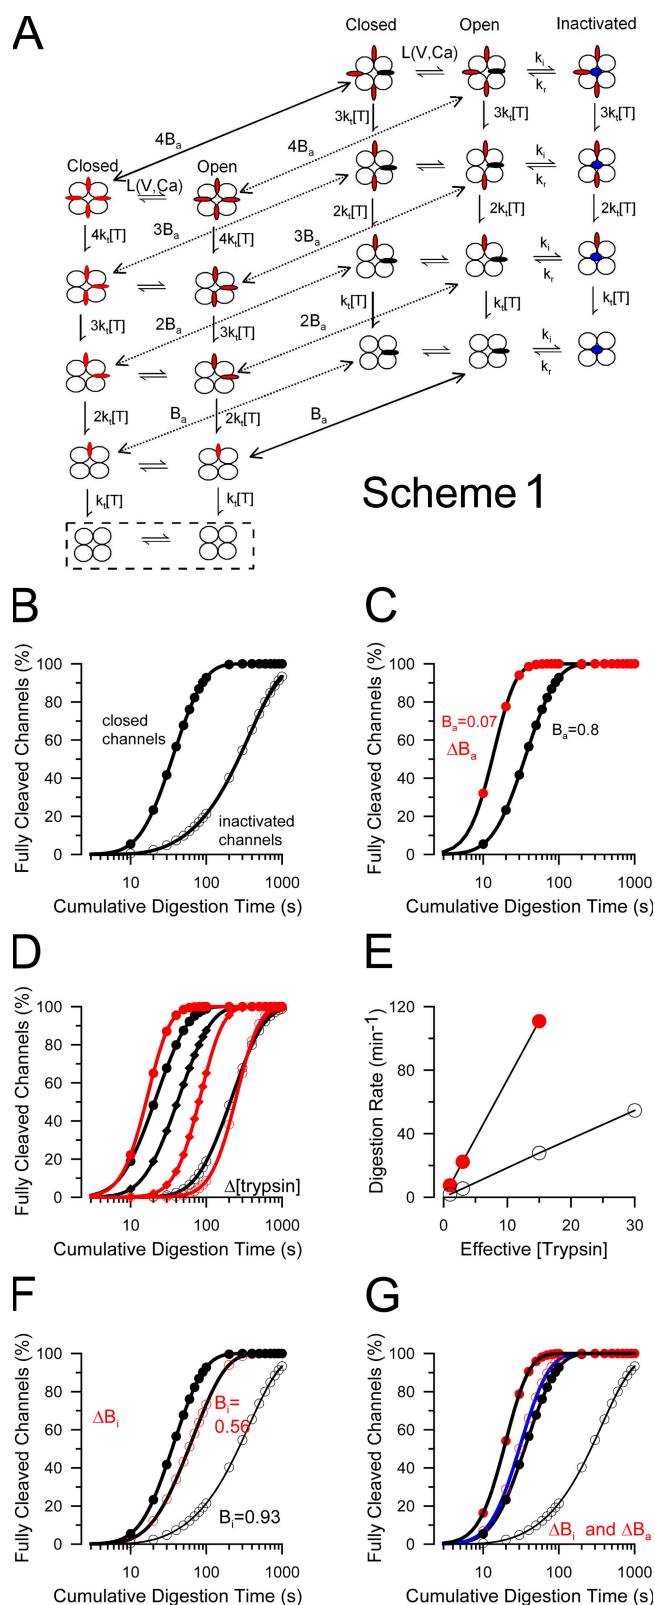

#### Online Supplemental Material

This manuscript contains additional material that provides further examples of the factors that contribute to accessibility of N-terminal domains to digestion by trypsin. In Fig. S1, the ability of a Kv $\beta 2$  N terminus to influence digestion by trypsin is illustrated. In Fig. S2, the trypsin digestibility of h $\beta 3a$  and h $\beta 3b$  are compared. In Figs. S3 and S4, the basic residues that are attacked by trypsin in the m $\beta 3a$  N terminus are defined. In Fig. S5, the failure of the  $\beta 2$  FIW motif to slow digestion of the  $\beta 3a$  N terminus is examined. The online supplemental material is available at <http://www.jgp.org/cgi/content/full/jgp.200810079/DC1>.

## RESULTS

Scheme 1 (Fig. 2 A) encapsulates the proposal that a single  $\beta$  subunit N terminus can transiently occupy a position protected from digestion by trypsin before moving to a position of inactivation. This model ignores the cases in which inactivation may occur directly without transient binding in the antechamber. The consequences of that omission are considered below. Fig. 2 (B–G) displays several predictions of this model based on parameters given in Table II. In Fig. 2 B, the basic expectations for Scheme 1 are shown both for closed-channel conditions and inactivating conditions. These predictions mirror previous experimental results and

analysis (Zhang et al., 2006). For closed-channel conditions, we mean those conditions of  $\text{Ca}^{2+}$  and voltage under which channels are predominantly in closed states alone, whereas by inactivating conditions we mean those conditions of voltage and  $\text{Ca}^{2+}$  where channels are almost exclusively in inactivated states. For inactivating conditions, the model predicts that the trypsin-mediated removal of inactivation is markedly slowed with the resulting power term,  $n$ , approaching 1.0, consistent with the idea that a single N terminus is protected during inactivation. We presume that protection during inactivation represents binding of a single N terminus to a position within the BK central cavity. If the affinity for binding within the antechamber is reduced (Fig. 2 C), both the digestion time course under closed-channel conditions is faster and the steepness of the digestion time course,  $n$ , is increased. This increase in  $n$  depends solely on the affinity of an N terminus for antechamber site and not on the overall rate of the digestion process (Fig. 2 D); when the effective rate is varied by changing the relative trypsin concentration,  $n$  is unaffected and the measured apparent rate of digestion varies linearly with trypsin concentration (Fig. 2 E). When binding in the central cavity is altered (Fig. 2 F), closed-channel protection is unaffected, but the protection conferred by inactivation is markedly reduced. In the illustrated example, protection produced by inactivation is almost abolished, even when current inactivates to a level that is  $<20\%$  of the peak current. Finally, when the affinities for both the central cavity site and the antechamber site are reduced (Fig. 2 G), shifts in both closed-channel

**Figure 2.** Stochastic model for protection of  $\beta 2$  N termini from digestion by trypsin. (A) A kinetic scheme describing the proposed digestion of  $\beta 2$  N termini by trypsin is shown, including channel gating ( $L(V, Ca)$ ), protection of N termini within the antechamber (P), and inactivation. States highlighted in the box are those in which inactivation has been completely removed by

protection and inactivated-mediated protection are predicted. These examples illustrate the varieties of behaviors in the digestion time course that might be expected as mutations of  $\beta 2$  N termini are examined. It should be noted that many of these predictions are not unique to a one-site protection model but are qualitatively characteristic of any model in which there is protection involving less than the full set of four N-terminal domains. Inclusion in Scheme 1 of a direct transition from open to inactivated states, thereby bypassing the antechamber binding site, has no impact on the predicted digestion behavior under closed-channel conditions, but will impact on the predicted digestion time course under inactivating conditions, dependent on various equilibrium constants. However, the basic idea that binding in the central cavity will slow digestion will apply regardless of the details of the relationship between central cavity and antechamber binding.

trypsin. Flattened red ovoids correspond to N termini in positions outside the antechamber, while, when black, are within the antechamber. Blue circles on the axes of the pore correspond to an N terminus in an inactivation position. (B–G) Simulated digestion time courses based on this scheme. (B) The simulated digestion time courses are shown for parameters given in Table II for closed-channel conditions ( $P_o = 0.01$ ) or inactivating conditions ( $P_o = 0.99$ ;  $B_i = 0.93$ ). The fit of Eq. 1 to the time course under closed-channel conditions yielded  $\tau_d = 28.5$  s ( $n = 2.09$ ). Under inactivating conditions,  $\tau_d = 327.3$  s ( $n = 1.17$ ). (C) The affinity of the N terminus for the site involved in closed-channel protection (affinity for antechamber,  $B_a$ ) was reduced by increasing the dissociation rate from the site 50-fold. Under these conditions (red circles),  $\tau_d = 7.2$  s ( $n = 3.98$ ). (D) The effective digestion rate was varied (approximating changes in [trypsin] [black symbols]) for closed-channel conditions as defined in A and for the case that antechamber binding affinity is reduced (red symbols). With reduced antechamber binding affinity, the slope of the digestion time course is steeper, but the slope is unaffected by the effective rate of the digestion process. (E) The effective digestion rates are plotted as a function of effective trypsin concentration for the cases of modest closed-channel protection (open circles) or without such closed-channel protection (red circles). The slope of the lines shows the approximately fourfold difference in effective digestion rate that arises because of the difference of occupancy in the antechamber, despite the fact that the same underlying molecular rate for the cleavage step was used in the two cases. (F) The effect of weakening the affinity of the inactivation domain for the channel pore ( $\Delta B_i$ ) is illustrated. The rate of dissociation of the inactivation domain from its blocking position was increased 10-fold, changing steady-state inactivation from 0.93 to 0.56. In this case, under inactivating conditions, the digestion time course (red circles) approaches that observed for closed-channel conditions (solid black circles) with  $\tau_d = 55.8$  s ( $n = 1.63$ ), whereas under there is no difference between the two cases for closed-channel conditions (not depicted). (G) The effect of a fivefold weakening of both binding in the antechamber ( $B_a$ ) and at the inactivation site ( $B_i$ ) is shown. This alters digestion both under closed-channel conditions (solid symbols;  $\tau_d = 11.1$  s;  $n = 3.43$ ) and under inactivated conditions (open symbols;  $\tau_d = 21.7$  s;  $n = 2.45$ ). Values for simulations and resulting measurements of  $\tau_d$  and  $n$  are given in Table II.

Po is the open probability defined by the closed-open equilibrium constant, L. k<sub>i</sub> is the forward rate of block by a single inactivation domain, with k<sub>r</sub>, the unblocking rate. B<sub>i</sub> reflects the fractional occupancy of the inactivation binding site conditions of high Po and saturation of the antechamber site. p<sub>r</sub> and p<sub>r</sub> are rates of binding and unbinding of an N terminal to the proposed antechamber site, with B<sub>a</sub> reflecting the fractional occupancy of the antechamber. k<sub>t</sub> is the rate of digestion of a single N terminus. τ<sub>d</sub> and n are the digestion time constant and power terms from fits of Eq. 1 to the digestion time course simulated with the given parameters. Because Eq. 1 is not an explicit derivation of the model used for simulation, τ<sub>d</sub> and n are not exact values, but the confidence limits on the fitted values were typically <1–4%.

It should also be kept in mind that protection of basic residues that occurs because of binding of N termini within the antechamber might arise from distinct mechanistic reasons. On one hand, binding in the antechamber of a portion of the N terminus may simply place basic residues within the antechamber making them inaccessible to digestion. Alternatively, binding of part of the N terminus in the antechamber may leave basic residues outside the boundaries of the antechamber, but the ability of trypsin to digest a freely mobile N terminus or a tethered N terminus may differ. In both cases, binding of a portion of the N terminus within the antechamber is required to achieve values of  $n \ll 4$ . However, whether closed-channel protection involves binding in the antechamber remains a hypothesis that the present results are designed to test.

#### A Mutation in the FIW Motif Speeds up Digestion under Closed-Channel Conditions and Increases the Power Term

Here, we test the idea that under closed-channel conditions a β2 N terminus can transiently occupy a position that protects it from digestion by trypsin. First, the model

predicts that if the fractional time that a β2 N terminus spends within the antechamber is decreased, the digestion time course should become faster. Second, if protection when channels are closed is sufficiently reduced, then n, the power term of the digestion time course, should approach 4. The initial hydrophobic sequence (MFIW) of the β2 N terminus, which is critical for inactivation (Xia et al., 2003), might influence residency time within an antechamber by interacting with other hydrophobic residues. We therefore examined β2 mutations either within or near the hydrophobic FIW triplet to determine whether any such manipulations might alter the time course of digestion by trypsin.

We first examined a construct in which tryptophan in position 4 was mutated to glycine (W4G). Inactivation is maintained in this construct, although with less steady-state block and more rapid unblock (Xia et al., 2003). The ability of trypsin to remove inactivation was examined by measuring BK currents before and after brief trypsin applications, as described previously (Zhang et al., 2006). Inactivation of α+β2(W4G) was so rapidly removed by 0.1 mg/ml trypsin that a time course could not be quantitatively defined. Reducing the trypsin

concentration to 0.01 mg/ml resulted in a removal of inactivation that could be compared with digestion of the wild-type  $\beta 2$  N terminus (Fig. 3, A and B). An effective rate of digestion was calculated based on the trypsin concentration and the measured digestion time constant. For wild-type  $\beta 2$ , the effective rate was  $0.7 (\pm 0.05) \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ , whereas for W4G the rate was  $5.4 (\pm 0.2) \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ , for an overall seven- to eightfold faster digestion of W4G (also see Fig. 11). Thus, although both wild-type  $\beta 2$  and W4G contain the same trypsin-digestible basic residues (R8 and R19), under closed-channel conditions the W4G construct is much more readily digested by trypsin. This unambiguously indicates that the tryptophan in position 4 stabilizes some conformation or position of the  $\beta 2$  N terminus that protects basic residues from attack by trypsin.

Another important aspect of the W4G digestion time course was that the fit to the digestion time course required a power term,  $n$ , that was clearly steeper than that for digestion of  $\beta 2$  currents (Fig. 3 E). For W4G,  $n = 3.45 \pm 0.13$ , whereas, for  $\beta 2$ ,  $n = 2.23 \pm 0.39$ . Plotting the digestion time course on a log-log scale illustrates clearly the steeper digestion time course for the W4G construct. This result supports the model of Fig. 2 A because  $n$  approaching 4 can only be obtained in cases when all

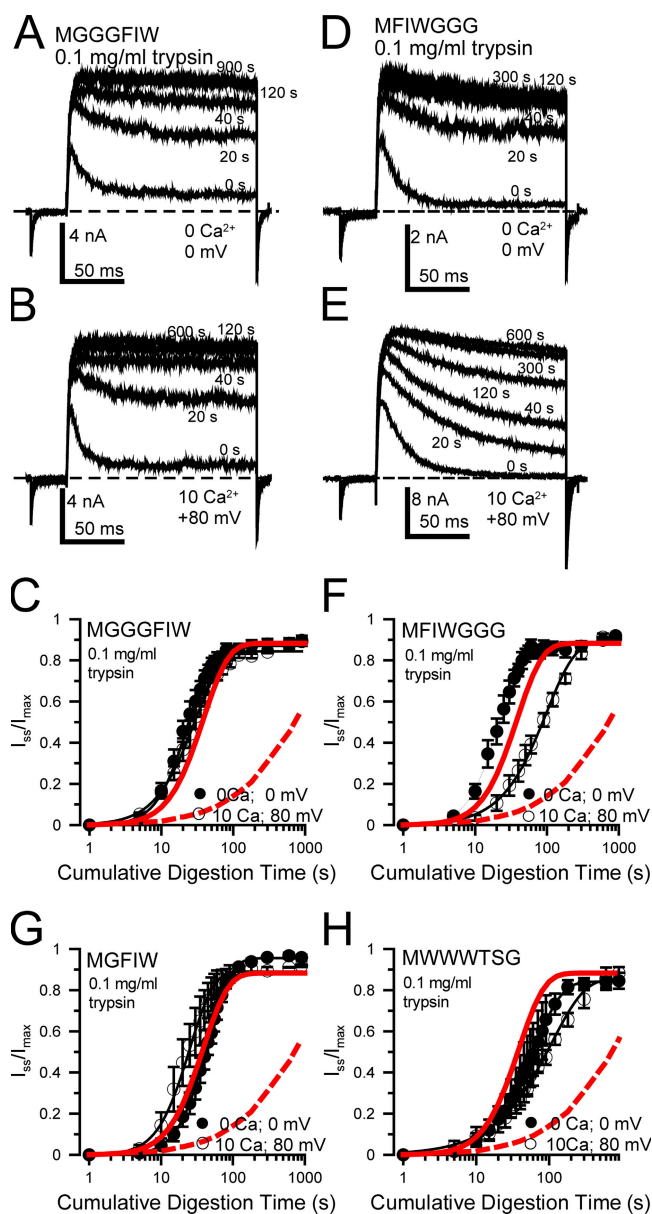

N termini can be similarly attacked by trypsin (Zhang et al., 2006). The change in the power term indicates that the difference in digestion between wild-type  $\beta 2$  and W4G arises not because of a change in conformation that occurs in all N termini, but rather from disruption of occupancy of site(s) of protection possibly within the antechamber.

We also examined digestion of W4G under conditions in which channels are largely inactivated ( $10 \mu\text{M Ca}^{2+}$ ,  $+80 \text{ mV}$ ; Fig. 3, C and D). For the W4G construct, conditions that promote inactivation failed to protect against digestion by trypsin. We attribute this largely to the fact that, in contrast to wild-type  $\beta 2$ , the level of steady-state current for W4G at  $10 \mu\text{M Ca}^{2+}$  and  $+80 \text{ mV}$  is substantial ( $I_{ss}$  at  $+80 \text{ mV}$  is  $\sim 10\text{--}25\%$  of the maximal conductance at  $+80 \text{ mV}$ ), such that the residency time of any N terminus within its inactivating position is brief. This is consistent with the predicted absence of inactivation-associated protection when the inactivation affinity is reduced (Fig. 2 F).

Collectively, the faster digestion  $\tau_d$  and the steeper power term are consistent with the idea that W4G N termini only transiently bind within the antechamber, such that all N termini can be readily digested. The fold increase in  $\tau_d$  observed between wild-type  $\beta 2$  and W4G

**Figure 3.** The W4G mutation in the  $\beta 2$  FIW motif speeds up trypsin-mediated removal of inactivation under closed-channel conditions. (A) Currents resulting from  $\alpha + \beta 2(\text{W4G})$  channels were activated by depolarizing steps to  $+80 \text{ mV}$  with  $10 \mu\text{M Ca}^{2+}$ . Between voltage steps, the patch was held at  $0 \text{ mV}$  with  $0 \text{ Ca}^{2+}$  and  $0.01 \text{ mg/ml}$  trypsin was applied for defined periods of time. Times given on the panel are the cumulative time of trypsin application. (B) The time course of digestion of  $\beta 2\text{-W4G}$  under closed-channel conditions with  $0.01 \text{ mg/ml}$  trypsin (black circles and line) is compared with the digestion of  $\beta 2$  wild type with  $0.02$ ,  $0.1$ , and  $0.5 \text{ mg/ml}$  trypsin (red lines). (C) Similar test traces are shown for a patch in which trypsin was applied in the presence of  $10 \mu\text{M Ca}^{2+}$  at  $+80 \text{ mV}$ , a condition in which  $\beta 2\text{-W4G}$  channels are  $>95\%$  inactivated. (D) The time course of removal of inactivation is plotted for sets of patches for the conditions shown in A and C. For comparison, the solid red line and dotted red line correspond, respectively, to the digestion of wild-type  $\beta 2$  N termini under closed-channel conditions ( $0 \mu\text{M Ca}^{2+}$ ;  $0 \text{ mV}$ ) with  $0.1 \text{ mg/ml}$  trypsin and under inactivating conditions ( $10 \mu\text{M Ca}^{2+}$ ;  $+80 \text{ mV}$ ) with  $0.1 \text{ mg/ml}$  trypsin. (E) The time course of digestion of  $\beta 2$  and  $\beta 2\text{-W4G}$  N termini is plotted on a log-log scale to compare the slope of the digestion process. For these fits, the power term for  $\beta 2$  digestion was  $2.23 \pm 0.39$ , and for  $\beta 2\text{-W4G}$  it was  $3.45 \pm 0.13$ .

**Figure 4.** Some manipulations of the  $\beta 2$  N terminus can alter inactivation-dependent protection against digestion, with minimal effects on rates of digestion during closed-channel conditions. (A) Traces show digestion at different times by 0.1 mg/ml trypsin applied in the presence of 0  $\text{Ca}^{2+}$  at 0 mV (closed-channel conditions) for the MGGGFIW construct. Displayed currents were obtained between trypsin applications with 10  $\mu\text{M}$   $\text{Ca}^{2+}$  as in Fig. 3. (B) Traces are shown for the MGGGFIW construct during digestion by 0.1 mg/ml trypsin in 10  $\mu\text{M}$   $\text{Ca}^{2+}$  at +80 mV (inactivated conditions). For this construct, at +80 mV, the steady-state non-inactivating current is  $\sim 30$ – $40\%$  of the maximal current. (C) The digestion time courses for MGGGFIW are plotted for the two conditions (black symbols, closed channel; open symbols, inactivated), along with the fitted results for the wild-type  $\beta 2$  subunit (dashed red line, inactivated conditions [10  $\mu\text{M}$   $\text{Ca}^{2+}$ ; 0 mV]; red line, closed-channel conditions [0  $\text{Ca}^{2+}$ ; 0 mV]). (D and E) Traces are shown for the MFIWGGG construct for digestion by 0.1 mg/ml trypsin either at 0  $\text{Ca}^{2+}$ , 0 mV (D) or at 10  $\mu\text{M}$   $\text{Ca}^{2+}$ , +80 mV (E). For MFIWGGG, the steady-state non-inactivating current at +80 mV is  $\sim 5\%$  of the maximal current.

(seven- to eightfold) is somewhat greater than predicted by Scheme 1 (two- to fivefold) in which only a single N terminus can occupy the protected site at a time (Zhang et al., 2006). Given that the power term for W4G was 3.4, some protection against digestion may still persist under closed-channel conditions for this construct. This indicates that an N terminus with no closed-channel-associated protection would be digested even more rapidly.

#### Mutations Near the FIW Motif Disrupt Inactivation-associated Protection against Trypsin Digestion, but Have Little Effect on Digestion under Closed-Channel Conditions

We next examined several constructs in which the hydrophobic motif (FIW) or the hydrophobicity was maintained (WWW) while other alterations near this motif were made (Fig. 4). Constructs MGGGFIW (Fig. 4, A–C), MFIWGGG (Fig. 4, D–F), MGFIW (Fig. 4 G), and MWWWTSG (Fig. 4 H) all exhibited control digestion time courses with 0.1 mg/ml trypsin that were generally similar to that of wild-type  $\beta 2$ , even though each construct differed substantially in the extent of steady-state inactivation observed at +80 mV and 10  $\mu\text{M}$   $\text{Ca}^{2+}$ . Thus, these changes in the  $\beta 2$  N terminus altered the apparent binding affinity of the inactivation domain for the central cavity binding site, but did not alter the time course of digestion by trypsin under closed-channel-associated conditions.

For MGGGFIW, there was little difference in the digestion time course either under closed-channel or inactivating conditions. This may arise because, at +80 mV, the steady-state current with 10  $\mu\text{M}$   $\text{Ca}^{2+}$  is  $\sim 40\%$  of the peak current (estimated from Xia et al., 2003), such that the duration of the inactivated state at +80 mV may be insufficient to produce protection. In contrast, MFIWGGG, for which the steady-state current at +80 mV with 10  $\mu\text{M}$   $\text{Ca}^{2+}$  is  $\sim 5\%$  of the peak current (Xia et al., 2003), does exhibit some inactivation-associated protection against digestion, although not as strong as for wild-type  $\beta 2$ . Both MGFIW and MWWWTSG show only slight differences between digestion under closed-channel conditions and inactivating conditions, again perhaps reflecting the relative instability of the inactivated state. The time course of digestion for MWWWTSG is actually slower than for wild-type  $\beta 2$ , with a shallower slope perhaps suggesting that the very hydrophobic WWW motif may enhance protection from digestion under closed-channel conditions. Overall, the extent to which inactivation-associated protection from digestion is reduced correlates with the amount of steady-state current relative to peak-inactivating current that is observed for a given construct at +80 mV and 10  $\mu\text{M}$   $\text{Ca}^{2+}$ .

(F) Digestion time courses are plotted for the MFIWGGG construct along with the time course for  $\beta 2$ . (G and H) Digestion time courses are plotted for MGFIW (G) and MWWWTSG (H), both under closed-channel and inactivating conditions.

Thus, in this case, channels may spend an appreciable fraction of time in open rather than inactivated states, such that protection from digestion is reduced.

These results indicate that the determinants that allow an N terminus to exhibit inactivation-associated protection can be dissociated from those that influence digestion under closed-channel conditions. This strongly supports the hypothesis that there are two distinct positions of binding of the N termini, one in a position associated with inactivation presumably in the central cavity and another possibly in the antechamber. The general behavior of these constructs can be rationalized within the context of Scheme 1 (Fig. 2 A), and the simulated behaviors (Fig. 2, B–G) accord with the basic idea that the affinities for the antechamber site and the inactivation site are independent.

Removal of residues FIW from the  $\beta 2$  N terminus results in a non-inactivating N terminus (Xia et al., 2003). Substitution of other inactivation-competent motifs might result in N termini that exhibited more rapid closed-channel digestion than wild-type  $\beta 2$  N termini. We created two constructs (Fig. S1A): one in which residues QVSIAR preceded the  $\beta 2$  FIW motif (Kv $\beta$ FIW), and a second one in which QVSIAR replaced the FIW motif (Kv $\beta$ 2TSG). QVSIAR corresponds to the first six residues after the initiation of methionine of the Kv $\beta$ 1.1 N terminus, an inactivation peptide of Kv1.2 (Zhou et al., 2001). Both constructs resulted in inactivation of BK channels with temporally distinct time courses (Fig. S1, B and D). For Kv $\beta$ FIW, the closed-channel digestion followed a time course virtually identical to wild-type  $\beta 2$  with 0.1 mg/ml trypsin (Fig. S1 C). This equivalence in digestion occurred despite the extra arginine residue that immediately preceded the FIW motif. In contrast, for the Kv $\beta$ 2TSG construct, the closed-channel digestion occurred with a rate similar to that of the  $\beta 2$ -W4G construct (Fig. S1 E). We also made a similar construct in which residues QVSIAR replaced FIW motif to remove the extra positive charge. The digestion time course was somewhat slower than in the case of QVSIAR, but still several-fold faster than for the wild-type  $\beta 2$  N terminus (see summary in Fig. 11). These results again suggest that the FIW motif of  $\beta 2$  helps maintain protection against digestion under closed-channel conditions, perhaps by stabilizing occupancy within the antechamber. In addition, the Kv $\beta$ 2TSG construct exhibited a steeper digestion time course compared with  $\beta 2$  ( $n = 4.43 \pm 0.39$  vs.  $n = 2.23 \pm 0.39$ ; Fig. S1 E). This supports the idea that the digestion time course of the native  $\beta 2$  N termini under closed-channel conditions reflects the binding of N termini to some site of protection.

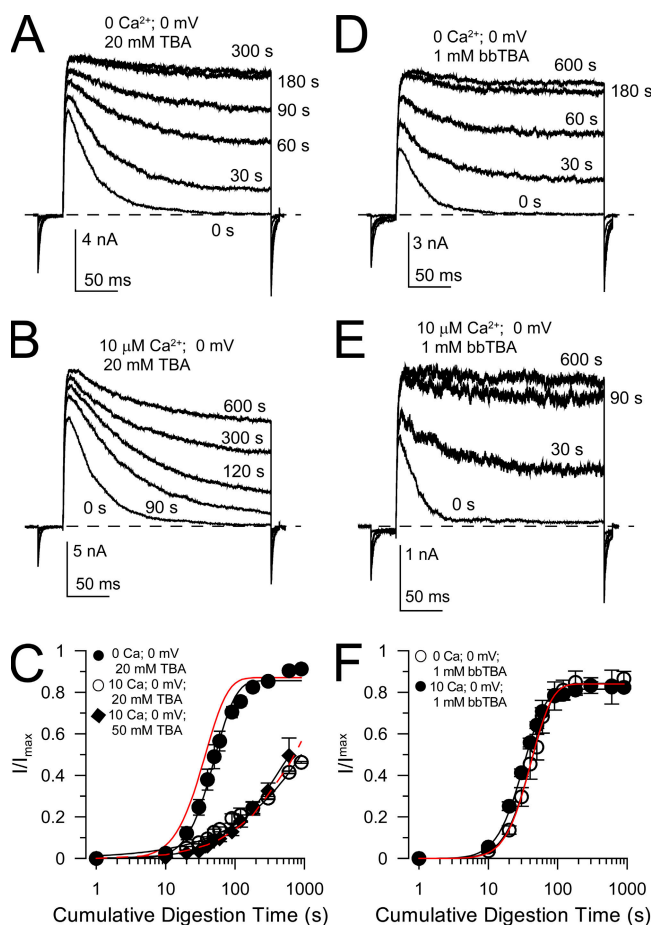

#### Quaternary Cytosolic Channel Blockers Do not Alter the Time Course of Removal of Inactivation by Trypsin under Closed-Channel Conditions

We hypothesized that cytosolic blockers of the BK central cavity might differentially affect the ability of trypsin to di-

gest N termini under closed-channel conditions compared with those examined under conditions that favor inactivation. We first tested the ability of tetrabutylammonium (TBA), a BK channel pore blocker (Li and Aldrich, 2004), to alter rates of digestion of  $\beta 2$  N termini (Fig. 5). With 20 mM TBA, the trypsin digestion time course of  $\beta 2$  N termini was similar to that in the absence of TBA both for closed channels (0  $\text{Ca}^{2+}$ , 0 mV) and for inactivated channels (10  $\mu\text{M}$   $\text{Ca}^{2+}$ , 0 mV; Fig. 5, A–C). The 0-voltage  $K_d$  for TBA block of BK channels has been estimated to be  $\sim 0.5$ –1 mM (Li and Aldrich, 2004; Wilkens and Aldrich, 2006), with stronger block at more positive potentials ( $z\delta = 0.21$ ). Our experiments yield an estimate of the  $K_d(0)$  for TBA block of  $\sim 0.69$  mM with  $z\delta \sim 0.12$  (unpublished data). For a single-site blocking model, the fractional occupancy of the open channel at 0 mV is calculated to be  $\sim 0.967$  with 20 mM TBA and  $\sim 0.986$  for 50 mM TBA. It is therefore unlikely that the lack of effect of TBA reflects incomplete pore occupancy. This result is reminiscent of the inability of cytosolic channel blockers to compete with native BK  $\beta$  subunit N-terminal inactivation (Solaro et al., 1997; Xia et al., 1999; Lingle et al., 2001).

We next examined the ability of a bulky quaternary ammonium blocker, bbTBA, to influence  $\beta 2$  digestion by trypsin. bbTBA inhibits BK channels with a weakly voltage-dependent  $K_d(0)$  of  $\sim 5$ –10  $\mu\text{M}$  with  $z\delta$  of 0.15 (Wilkens and Aldrich, 2006), which is identical to our estimates of 5.0  $\mu\text{M}$  and 0.11 (unpublished data). 1 mM bbTBA did not alter the trypsin-mediated removal of inactivation under closed-channel conditions but completely abolished the inactivation-associated protection against digestion (Fig. 5, D–F). Assuming single-site block of the open BK channel, the fractional occupancy by 1 mM bbTBA is calculated to be 0.995 at 0 mV.

We interpret these results as follows. It is known that the binding site for the rate-limiting step in inactivation mediated by the  $\beta 2$  N terminus is not inhibited by smaller quaternary ammonium blockers (Xia et al., 1999; Lingle et al., 2001). This presumably arises because of the two-step nature of the BK inactivation process in which the formation of a pre-inactivated open state precedes the transition to the inactivated state (Lingle et al., 2001; Benzinger et al., 2006). In this model ( $C \rightleftharpoons O \rightleftharpoons O^* \rightleftharpoons I$ ), the transition to  $O^*$  is the rate-limiting step in inactivation (Lingle et al., 2001). If small quaternary blockers bind equally well to both  $O$  and  $O^*$ , they will have no impact on the apparent time course of the inactivation process. Thus, although TBA may occupy a pore-blocking position, it may not inhibit the ability of the N terminus to form the pre-inactivated open state. In contrast, bbTBA, by occupying a larger volume within the BK central cavity, apparently does impede the ability of  $\beta$  subunit N termini to reach a binding site. Finally, the inability of either TBA or bbTBA to substantially alter the rate of digestion by trypsin under closed-channel conditions supports

**Figure 5.** Inactivation-associated protection against digestion by trypsin is differentially sensitive to cytosolic channel blockers. (A) Traces show test sweeps at different time points during digestion of  $\beta 2$  by 0.1 mg/ml trypsin under conditions of low activation (0  $\text{Ca}^{2+}$ ; 0 mV) but in the presence of 20 mM TBA. (B) Traces show test sweeps during digestion of  $\beta 2$  by 0.1 mg/ml trypsin with 20 mM TBA under inactivating conditions (10  $\mu\text{M}$   $\text{Ca}^{2+}$ ; 0 mV). (C) The time course of removal of inactivation is plotted for the indicated conditions. Neither 20 nor 50 mM TBA abolishes the inactivation-associated slowing of digestion. The red lines show the normal removal of inactivation of  $\beta 2$  subunits with 0.1 mg/ml trypsin in the absence of TBA for closed-channel (solid line) and inactivating (dotted line) conditions. (D) Traces show removal of  $\beta 2$ -mediated inactivation by 0.1 mg/ml trypsin applied under closed-channel conditions, but with 1 mM bbTBA. (E) The digestion by 0.1 mg/ml trypsin occurred at 0 mV, 10  $\mu\text{M}$   $\text{Ca}^{2+}$ , with 1 mM bbTBA. (F) The time course of removal of  $\beta 2$ -mediated inactivation is plotted for closed-channel and inactivating conditions, both with 1 mM bbTBA, showing the ability of bbTBA to prevent the inactivation-associated protection from digestion while not changing the digestion rate under closed-channel conditions.

the view that the site(s) of  $\beta 2$  interaction that is involved in defining closed-channel protection is distinct from any binding sites within the central cavity.

#### Trypsin Sensitivity of a Wild-type Mouse $\beta 3a$ Inactivation Domain greatly Exceeds that of the Wild-type Human $\beta 2$ Inactivation Domain

N termini from different inactivating BK  $\beta$  subunits may differ in the rates of trypsin-mediated removal of inacti-

vation based on differences in affinities for interaction within the antechamber. We therefore compared the trypsin sensitivity of inactivation mediated by the human  $\beta 2$  subunit (Fig. 6, A–C) with the mouse  $\beta 3a$  subunit (Fig. 6, D–F). As with the  $\beta 2$ -W4G construct, removal of inactivation mediated by  $\beta 3a$  subunits with 0.1 mg/ml trypsin was so fast that a time course could not be readily defined. Reduction of the trypsin concentration to 0.01 mg/ml resulted in a removal of inactivation (Fig. 6, D–F) that followed a time course similar to digestion of the  $\beta 2$  N terminus by 0.1 mg/ml trypsin (Fig. 6, A–C). When trypsin was applied during inactivating conditions, the digestion of  $\beta 3a$  N termini was slowed (Fig. 6 E), also similar to the behavior of  $\beta 2$  N termini (Fig. 6 B). In both cases, under inactivating conditions, the power term for the fit to the digestion time course approached one, consistent with the idea that the dissociation of a single N terminus becomes rate limiting for digestion by trypsin.

Time constants for digestion of m $\beta 3a$  were determined at multiple trypsin concentrations (Fig. 7 A) and compared with previous estimates obtained for h $\beta 2$  (Zhang et al., 2006). For both subunits, the digestion rate was plotted as a function of [trypsin] (Fig. 7 B). For  $\beta 3a$ , the digestion rate varied approximately linearly with [trypsin], with a slope of  $9.97 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ . For  $\beta 2$  (Zhang et al., 2006), the limiting slope at low concentration was  $6.82 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ , suggesting that there is a >10-fold difference between the digestion rates. Another important difference was that the power term in the fit to the removal of inactivation of m $\beta 3a$  currents was clearly steeper than for  $\beta 2$  currents (Fig. 7 C), except with the highest tested trypsin concentration. As with  $\beta 2$ , TBA and bbTBA had differential effects on inactivation-associated protection against  $\beta 3a$  N-terminal digestion (Fig. 8). Whereas TBA was without effect on inactivation-associated protection (Fig. 8, A and B), bbTBA abolished the protection produced by inactivation (Fig. 8, C and D). No clear effects on closed-channel digestion were produced by either TBA or bbTBA.

We also examined the trypsin-mediated removal of inactivation of other N termini. The time course of removal of inactivation by 0.1 mg/ml trypsin for both h $\beta 3a$  and h $\beta 3b$  N termini is comparable to, but somewhat slower than, for digestion of h $\beta 2$  (Fig. S2).

#### Determinants of Digestion Rates of the $\beta 3a$ N Terminus

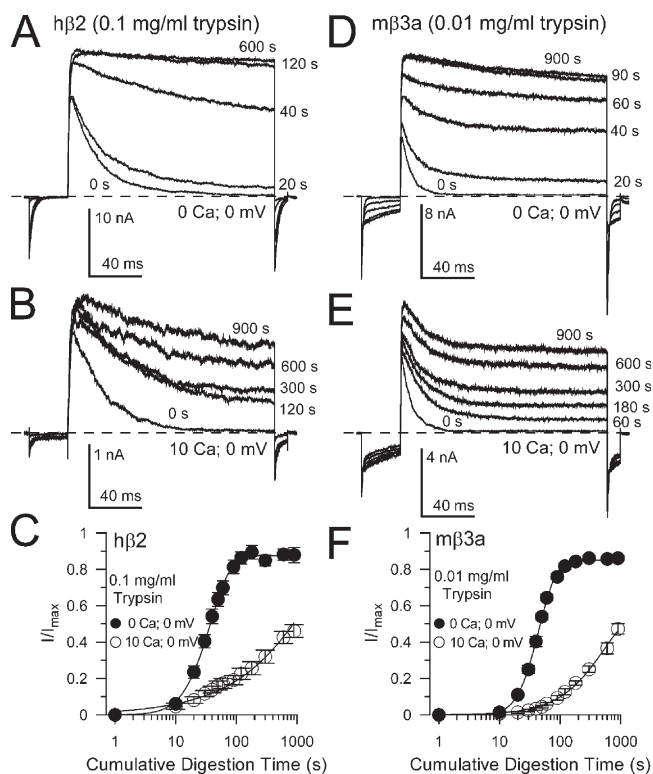

The faster digestion of the  $\beta 3a$  N terminus with steeper digestion time course is consistent with the idea that, under closed-channel conditions, the  $\beta 3a$  N terminus may have a reduced occupancy of the antechamber compared with the  $\beta 2$  N terminus. However, one might imagine other explanations. For example, the  $\beta 3a$  N terminus may contain a greater number of accessible basic residues than the  $\beta 2$  N terminus.

Effects of mutations of basic residues in the  $\beta 3a$  N terminus on the trypsin sensitivity were therefore examined (see Fig. 11 for summary and Table I for constructs).

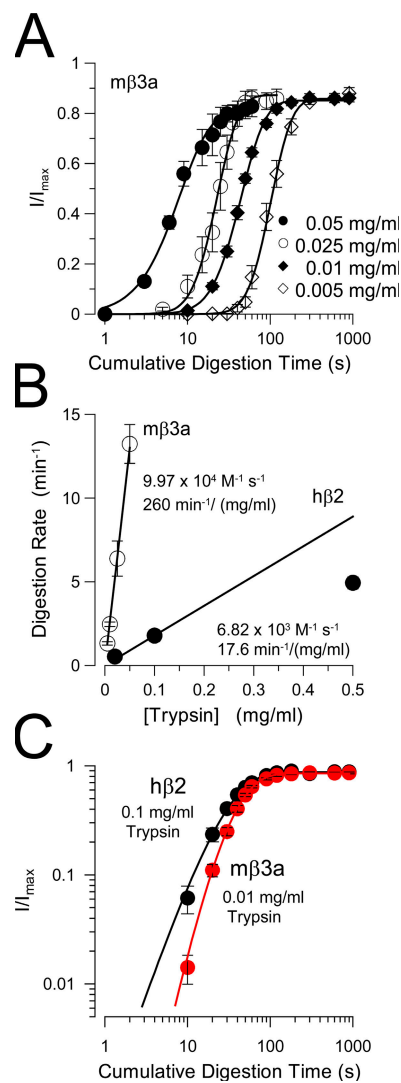

The  $\beta 3a$  N terminus contains four basic residues, R16–18 and R21 (Table I), arising from the  $\beta 3a$ -specific N terminus, and then three other basic residues, K29, K36, and K40, shared in common with the  $\beta 3b$  N terminus. We first examined constructs in which multiple basic residues were simultaneously neutralized. Mutation of K29Q, K36Q, and K40Q, or only K36Q and K40Q, resulted in constructs that were digested only slightly more slowly than wild-type  $\beta 3a$  (Fig. S3 A). In contrast, mutation of R16–18Q and R21Q resulted in an inactivating construct that was hardly affected over 15 min of application of 0.1 mg/ml trypsin (Fig. S3 B). When only R16–R18 were neutralized to Q, digestion with 0.01 mg/ml trypsin persisted, although it was shifted ( $\tau_d = 91.6 \pm 9.6$  s) several-fold relative to wild-type  $\beta 3a$  ( $23.7 \pm 1.4$  s). Because K29, K36, and K40 contribute negligibly to digestion by trypsin,

this suggests that residue R21 is at least one likely target of trypsin action.

We next examined constructs in which only a single basic residue was mutated or a single basic residue was

**Figure 6.** Digestion of  $m\beta 3a$  N termini is much faster than for  $\beta 2$ . (A) Traces show removal of  $h\beta 2$ -mediated inactivation under closed-channel conditions (0  $\text{Ca}^{2+}$ ; 0 mV) with 0.1 mg/ml trypsin. (B) Traces show removal of  $\beta 2$ -mediated inactivation by 0.1 mg/ml trypsin under inactivating conditions (10  $\mu\text{M}$   $\text{Ca}^{2+}$ ; 0 mV). (C) The digestion time course is plotted for both closed (solid circles) and inactivating (open circles)  $h\beta 2$  channels. (D) Sweeps monitor removal of  $m\beta 3a$ -mediated inactivation under closed-channel conditions, but with 0.01 mg/ml trypsin. Trypsin abolishes both the slow  $\beta 3a$  tail currents and removes inactivation. (E) The time course of removal of  $m\beta 3a$ -mediated inactivation by 0.01 mg/ml trypsin is shown under inactivating conditions. Note that even at 900 s, appreciable inactivation still remains and that the slow  $\beta 3a$  tail current persists. (F) The digestion time course for  $m\beta 3a$  channels is plotted for both closed-channel (solid circles) and inactivating (open circles) conditions.

**Figure 7.** Comparison of removal of inactivation mediated by  $h\beta 2$  and  $m\beta 3a$ . (A) The removal of  $m\beta 3a$ -mediated inactivation is plotted for four different trypsin concentrations. Fitted time constants of digestion were  $5.83 \pm 1.2$  s (0.05 mg/ml),  $10.5 \pm 1.42$  s (0.025 mg/ml),  $23.72 \pm 1.41$  s (0.01 mg/ml), and  $44.22 \pm 3.74$  s (0.005 mg/ml). (B) The effective digestion rate ( $\text{min}^{-1}$ ) is plotted as a function of trypsin concentration for both  $m\beta 3a$  and  $h\beta 2$  (from Zhang et al., 2006). The line through the  $m\beta 3a$  points corresponds to a linear fit with a slope of  $260 \text{ min}^{-1}/\text{mg/ml}$ , which assumes a molecular weight of 24 kD for trypsin corresponds to  $9.97 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ . For  $\beta 2$ , the line corresponds to the slope through the two lowest trypsin concentrations, yielding a maximal effective rate of  $6.82 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ . (C) A log-log plot of the digestion time course for  $h\beta 2$  (black circles) and  $m\beta 3a$  (red circles) compares the slope of the digestion process. For  $\beta 2$ ,  $n = 2.21 \pm 0.23$ ; for  $\beta 3a$ ,  $n = 3.62 \pm 0.39$ . Note that in A, except for the time course observed with 0.05 mg/ml, the steeper slope of  $\beta 3a$  digestion is independent of trypsin concentration. Similarly, the slope of  $\beta 2$  digestion is independent of trypsin concentration (not depicted).

retained in the N terminus (Fig. S4). When residue R16, R17, R18, or R21 was individually mutated to Q, the resulting constructs retained a sensitivity to 0.01 mg/ml trypsin that was only slightly less than wild-type m $\beta$ 3a, with mutation of R18 and R21 having somewhat stronger effects than mutation of R16 and R17 (Fig. S4, A and B). However, when both R18 and R21 were mutated to Q, the resulting trypsin sensitivity was shifted  $\sim$ 10-fold (Fig. S4 C). We also examined constructs in which only a single basic residue was retained in the N terminus. In m $\beta$ 3a-R16 and m $\beta$ 3a-R17, 0.1 mg/ml trypsin removed inactivation with a time course similar to or slower than that of the effect of 0.01 mg/ml trypsin on wild-type m $\beta$ 3a (Fig. S4 D). However, when only R21 (m $\beta$ 3a-R21) was retained in the N terminus, 0.01 mg/ml trypsin removed inactivation with a time course only somewhat slower than for wild-type m $\beta$ 3a (Fig. S3 E), whereas R18 (m $\beta$ 3a-R18) more weakly supported digestion by 0.01 mg/ml trypsin. When a construct retained only R18 and R21 in the N terminus (m $\beta$ 3a-R18 and -R21),

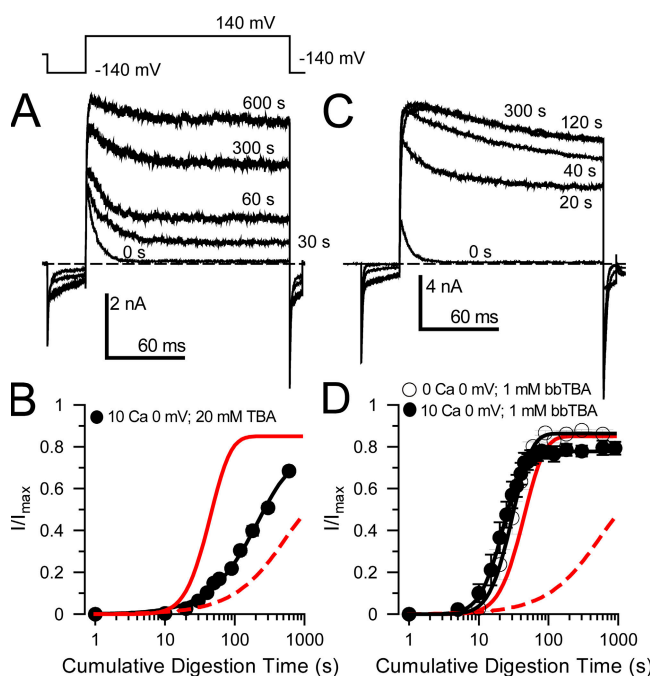

digestion by 0.01 mg/ml trypsin was essentially indistinguishable from wild-type m $\beta$ 3a (Fig. S4 F). These results indicate that R18 and R21 are probably the primary residues attacked by trypsin in the m $\beta$ 3a N terminus, but, even in the absence of R18 and R21, both R16 and R17 will support digestion at rates comparable to the  $\beta$ 2 N terminus.

These results show that two specific basic residues are largely responsible for wild-type m $\beta$ 3a digestion rates. This is the same number of attackable basic residues as in the wild-type  $\beta$ 2 N terminus, despite the fact that the m $\beta$ 3a N terminus is digested at about a 10-fold faster rate than the  $\beta$ 2 N terminus. We conclude that the number of digestible m $\beta$ 3a basic residues is not the reason that the m $\beta$ 3a N terminus is more rapidly digested.

#### Accounting for the Differences in Trypsin Digestion Rates of $\beta$ 3a and $\beta$ 2

The initial segments of both the  $\beta$ 2 and  $\beta$ 3a N termini are largely hydrophobic. We therefore examined the consequences of exchange or addition of these segments on each N terminus. In one case, we simply appended the first seven  $\beta$ 2 residues FIWTSGR to the  $\beta$ 3a N terminus to determine whether this might confer  $\beta$ 2-like behavior on  $\beta$ 3a. A related construct (FIWTSGQ) was also examined to remove the possible contribution of the  $\beta$ 2 R8 arginine to the digestion process. Both FIWTSGR- $\beta$ 3a (Fig. 9 A) and FIWTSGQ- $\beta$ 3a (Fig. 9 B) exhibit sensitivity to digestion by 0.01 mg/ml trypsin, which is similar to wild-type  $\beta$ 3a. Thus, the presence of the FIW motif, albeit at some distance from digestible  $\beta$ 3a residues, has essentially no effect on the digestion rate. We also undertook a variety of other manipulations all using the addition of the FIW motif, but with other alterations in the  $\beta$ 3a N terminus (Fig. S5). In all cases, trypsin removed inactivation with a time course more similar to that of wild-type m $\beta$ 3a than of  $\beta$ 2. Given the view that the FIW motif of the  $\beta$ 2 N terminus binds within the antechamber, it seems likely that the FIW motif can also act similarly in at least some of these constructs. These results therefore suggest that the  $\beta$ 3a N terminus, even when binding within the antechamber, may remain readily digestible by trypsin.

We then replaced the first 12 residues of the  $\beta$ 2 N terminus with the first 12, largely hydrophobic residues of the  $\beta$ 3a N terminus (m $\beta$ 3a<sub>1-12</sub>/ $\beta$ 2<sub>13-end</sub>). This construct lacks the digestible R8 residue found in  $\beta$ 2, and so therefore should be compared with mutated  $\beta$ 2 constructs containing only the digestible R19 residue. This construct (Fig. 9 C) exhibited a sensitivity to 0.1 mg/ml trypsin ( $\tau_d = 18.0 \pm 0.90$  ms) that was comparable to wild-type  $\beta$ 2, but approximately two- to fourfold faster than digestion of  $\beta$ 2 constructs containing only R19 (Zhang et al., 2006). Furthermore, m $\beta$ 3a<sub>1-12</sub>/ $\beta$ 2<sub>13-end</sub> exhibited a somewhat steeper digestion time course ( $n = 3.3 \pm 0.3$ ) reminiscent of  $\beta$ 3a. The  $\beta$ 3a N terminus

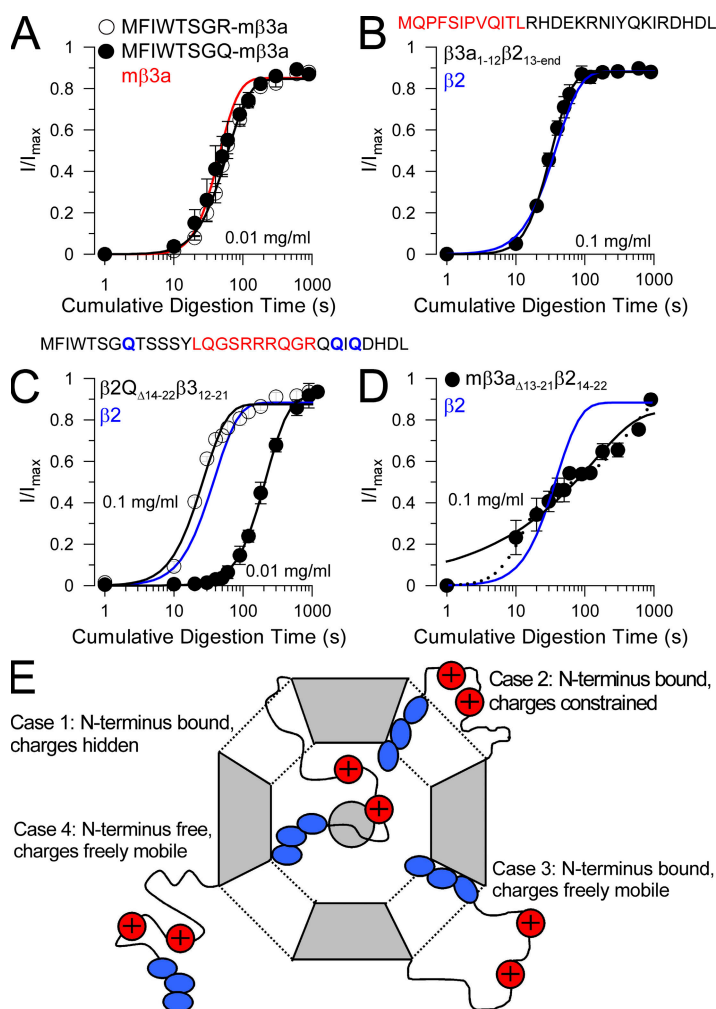

**Figure 8.** bbTBA and TBA differentially influence inactivation-associated protection against trypsin digestion for  $\beta$ 3a subunits. (A) Traces show progressive removal by 0.01 mg/ml trypsin of inactivation mediated by  $\beta$ 3a subunits with 20 mM TBA applied together with trypsin under inactivating conditions (10  $\mu$ M  $\text{Ca}^{2+}$ ; 0 mV). (B) The time course of the digestion process under inactivating conditions with TBA is compared with the normal time course of digestion of  $\beta$ 3a under closed-channel (red line) or inactivated (dotted red line) conditions. (C) Traces show removal of inactivation when 0.01 mg/ml trypsin was applied along with 1 mM bbTBA under inactivating conditions. (D) Time course plots of removal of inactivation show that 1 mM bbTBA abolishes the protection normally produced by inactivation (dotted red line), but has little effect on the digestion time course (red line) under closed-channel conditions.

therefore partially substitutes for the FIW motif in constraining digestion of basic residues in the  $\beta 2$  N terminus, although perhaps binding somewhat more weakly within the antechamber.

If elements of both  $\beta 3a$  and  $\beta 2$  N termini support antechamber binding, why are the two N termini digested at such apparently different rates and with such different power terms ( $n$ )? One possibility is that, although the hydrophobic part of both N termini may transiently bind within the antechamber, perhaps the segments containing the digestible basic residues (in  $\beta 2$ , R8 and R19; in  $\beta 3$ , R18 and R21) are not similarly accessible to trypsin when the N terminus is bound. Perhaps for the  $\beta 2$  N terminus, binding within the antechamber stabilizes a structure that is more resistant to digestion of the key basic residues than in a freely mobile N terminus. In contrast, for the  $\beta 3a$  N terminus, perhaps the basic residues of bound  $\beta 3a$  N termini retain sufficient flexibility to be indistinguishable from freely mobile N termini. To test the idea that the segments containing the basic residues might behave differently between the two N termini, segments containing previously identified trypsin-digestible basic residues were swapped between subunits. First, residues 12–21 from  $\beta 3a$

replaced residues 14–22 in a  $\beta 2$  construct in which the 10 N-terminal basic residues were mutated to Q ( $\beta 2$ -10Q $_{\Delta 14-22}$  $\beta 3a_{12-21}$ ). In this construct, trypsin-mediated digestion was slightly faster than wild-type  $\beta 2$  (Fig. 9 C), although clearly slower than for m $\beta 3a$ . Similarly, a segment of  $\beta 2$  residues (14–22) was used to replace residues 13–21 in  $\beta 3a$  (construct m $\beta 3a_{\Delta 13-21}$  $\beta 2_{14-22}$ ), such that the digestible R19 residue from  $\beta 2$  replaced the set of digestible residues in  $\beta 3a$ . In this case (Fig. 9 D), removal of inactivation digestion with 0.1 mg/ml exhibited a complex time course perhaps best fit by two digestion components, one somewhat faster and one slower than for wild-type  $\beta 2$ . Although we have no simple explanation for this behavior, compared with the digestion of wild-type  $\beta 3a$ , the result suggests that replacement of the digestible segment of  $\beta 3a$  with a segment from  $\beta 2$  does make the resulting construct somewhat less vulnerable to digestion by trypsin.

Although the above experiments fail to account fully for the difference in digestion rates of the two N termini, some conclusions can be drawn. First, the initial segment of the  $\beta 3a$  N terminus does appear to substitute for the initial segment of the  $\beta 2$  N terminus in supporting inactivation and maintaining a digestion rate

**Figure 9.** Exchange of hydrophobic and charged segments between  $\beta 2$  and h $\beta 3a$  N termini. (A) The time courses of digestion under closed-channel conditions (0  $Ca^{2+}$ ; 0 mV) of the MFIWTSGR- $\beta 3a$  and MFIWTSGQ- $\beta 3a$  constructs are compared with wild-type m $\beta 3a$  (red line) for 0.01 mg/ml trypsin. (B) The time course of digestion of  $\beta 3a_{1-12}\beta 2_{13-end}$  (MQPFSIPVQITL from  $\beta 3a$  appended to  $\beta 2$  at position 13) with 0.1 mg/ml trypsin is compared with the  $\beta 2$  digestion time course. (C) A  $\beta 3a$  segment (residues 12–21 containing R16–18 and R21) replaced residues 14–22 in a  $\beta 2$  construct in which all N-terminal basic residues were replaced with Q. The plot shows the digestion time course for both 0.1 and 0.01 mg/ml trypsin compared with that of  $\beta 2$  (blue line). (D) The time course of digestion with 0.1 mg/ml trypsin of construct m $\beta 3a_{13-21}\beta 2_{14-22}$  is compared with that of  $\beta 2$  (blue line). Dotted line represents a two-component exponential fit (analogous to Eq. 1) to the digestion time course, and the solid represents a fit of Eq. 1. (E) Possible configurations of N termini in a closed channel are schematized. Case 1, an N terminus is bound in the antechamber, and basic residues are shielded from digestion; Case 2, the N terminus is bound in the antechamber, but, although basic residues are outside the antechamber, they are structurally constrained, thereby hindering digestion; Case 3, the N terminus is bound in the antechamber, but basic residues are freely mobile and accessible to attack by trypsin; Case 4, an N terminus is freely mobile outside the antechamber allowing easy digestion by trypsin.

comparable to  $\beta 2$ . This suggests that the  $\beta 3a$  N terminus does bind within the antechamber, but perhaps with somewhat weaker affinity. Second, the digestible basic residues in the  $\beta 2$  N termini appear less readily digested than those of the  $\beta 3a$  N terminus, although the addition of the  $\beta 3a$  segment with basic residues produces only a slight increase in digestibility. The failure to observe a complete swap in properties may arise simply because of the limitations of the approach, in which a segment transferred from one N terminus to another may behave differently in the new background.

Within the context of Scheme 1, one might imagine that any given N terminus might adopt any of several possible configurations when channels are closed, each of which may differentially influence digestibility by trypsin. Fig. 9 E diagrams four possible situations. In Case 1, the binding of an N terminus within the antechamber may position basic residues within the antechamber, thereby effectively hiding the basic residues from attack by trypsin. In Case 2, when an N terminus is bound within the antechamber, it may constrain movement of the basic residues such that they are less vulnerable to attack by trypsin. In Case 3, when an N terminus is bound, the segment containing basic residues may reside outside the antechamber and be fully vulnerable to attack by trypsin. In Case 4, an unbound N terminus may be entirely outside the antechamber volume, with basic residues fully vulnerable to attack by trypsin within any constraints arising from any native N-terminal structure. For any N terminus in which the power term,  $n$ , for digestion is 2–3, the implication is that N termini that are bound within the antechamber are digested at slower rates than the freely mobile N termini outside the antechamber. However, the requirement of slower digestion is met by either Case 1 or Case 2, whereas Case 3 would be expected to produce little, if any, protection against trypsin digestion.  $m\beta 3a$  exhibits a faster digestion than  $\beta 2$  and contains the same number of digestible basic residues (two), and the  $m\beta 3a$  hydrophobic segment does appear to substitute with the FIW motif in supporting protection of digestion under closed-channel conditions for an otherwise  $\beta 2$  N terminus. Based on these differences, we propose that, under closed-channel conditions, the  $m\beta 3a$  N terminus behaves in a fashion similar to Case 3, whereas for  $\beta 2$  the N terminus behaves similarly to Case 2 (or perhaps Case 1). The failure of the  $\beta 3a_{12-21}$  segment to markedly increase  $\beta 2$  digestion may arise because the residual part of the  $\beta 2$  N terminus confers structural constraints on the  $\beta 3a$  segment, thereby minimizing access of trypsin to this segment.

#### Protection under Closed-Channel Conditions May Arise because of Constraints on Motion of the N Terminus when Tethered at a Site within the Antechamber

Guided by the above models for N-terminal behavior in closed channels, we used a second approach to examine properties of protection against trypsin digestion under

closed-channel conditions. In previous experiments, we examined the trypsin sensitivity of artificial N termini in which pairs of basic residues were positioned at different distances from an FIW inactivation segment (Zhang et al., 2006). These experiments showed that, when basic residues were <12 positions from the FIW motif, in inactivated channels those basic residues were in a position that could not be cleaved by trypsin. However, under closed-channel conditions, artificial N termini were digested at rates very comparable to digestion of  $\beta 2$  N termini under similar conditions. For the  $\beta 2$  N terminus, one might imagine that during binding within the antechamber some structure of the N terminus might preclude attack by trypsin even if the basic residues were outside the antechamber, but this explanation seems less likely for artificial N termini. Specifically, one might expect that artificial N termini would be sufficiently flexible that any basic residues positioned outside the antechamber under closed-channel conditions would be readily attacked by trypsin, therefore predicting a more rapid and steeper digestion time course than for the wild-type  $\beta 2$  N terminus. Yet, for an extensive set of artificial N termini (Zhang et al., 2006), the digestion of the artificial N termini exhibited power terms in the range of 1.5 to 2.5, with time constants comparable to the wild-type  $\beta 2$  N terminus. Because it seems likely that the basic residues for some of these constructs are outside the antechamber under closed-channel conditions, why are these power terms so low? Case 2 of Fig. 9 E would provide one possible explanation. For this to be the case, the poly-Q linkers used here must have structural constraints that reduce accessibility of trypsin to basic residues.

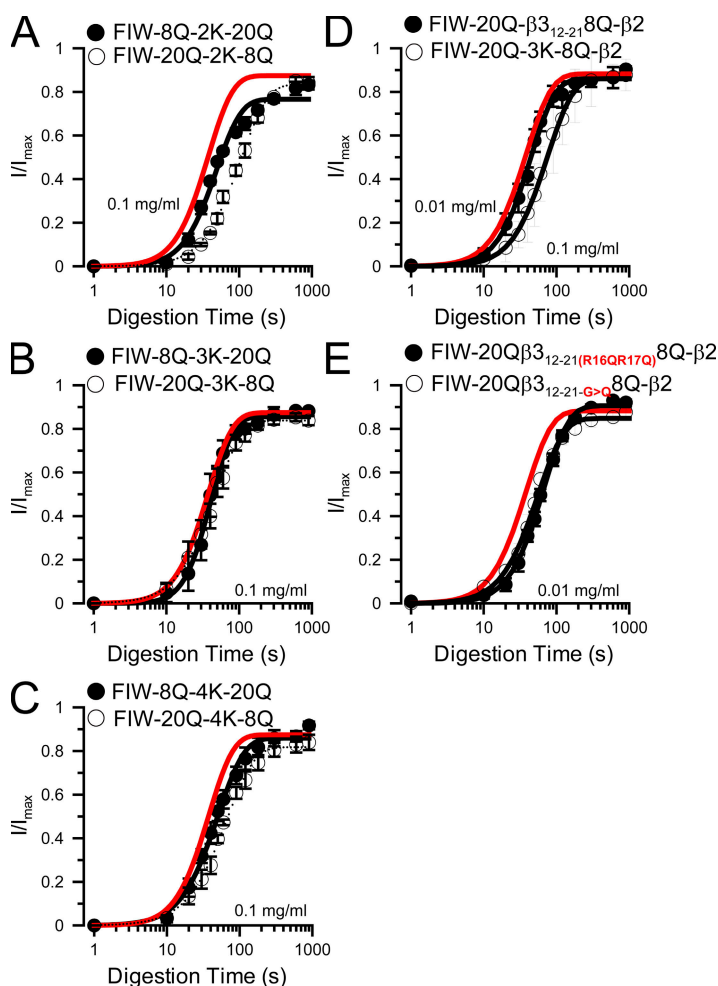

To further address this issue, we have created new artificial N termini in which basic residues are positioned either 8 residues (FIW-8Q-nK-20Q constructs) or 20 residues (FIW-20Q-nK-8Q constructs) from the FIW segment (Table I). Furthermore, we made versions of these constructs in which either two, three, or four basic residues were inserted. A variety of results seemed possible. If a 20Q spacer between basic residues and FIW is more likely to position the basic residues outside the antechamber, one might expect that the digestion rate under closed-channel conditions might be faster than in constructs with the 8Q spacer. If both 20Q and 8Q spacers position basic residues outside the antechamber, the closed-channel-associated digestion in both cases might be expected to be faster than for wild-type  $\beta 2$ . Contrary to either of these expectations, the digestion time course was generally similar for constructs with either a 20Q or 8Q spacer (Fig. 10, A–C) regardless of whether there were two, three, or four basic residues on the N terminus. Furthermore, in all cases the digestion time course under closed-channel conditions was quite comparable to that of the wild-type  $\beta 2$  N terminus regardless of whether there were two, three, or four basic residues.

We think it is unlikely that this closed-channel protection can be explained by the idea that the basic residues in both the 8Q and 20Q constructs are positioned within the antechamber. If, on the contrary, the basic residues in the 20Q-xK-8Q constructs are positioned outside the antechamber, the persistent closed-channel protection might arise from contributions of the two factors mentioned above. First, when an N-terminal binding epitope binds within the antechamber, that binding may reduce the overall flexibility of the N terminus and, by minimizing the degrees of freedom of motion of that N terminus, reduce the likelihood of attack by trypsin. Second, the poly-Q linkers may adopt conformations that reduce accessibility of basic residues to attack by trypsin. Both of these explanations are consistent with Case 2 (Fig. 9 E). Overall, the results seem most consistent with the idea that protection under closed-channel conditions does not arise from the presence of the basic residues within the antechamber, but rather from structural constraints on the accessibility of trypsin to the digestible basic residues when an N terminus is bound within the antechamber.

If this hypothesis is correct, the digestion rate of an artificial N terminus under closed-channel conditions

might be increased if the basic residues were embedded in a more flexible set of residues. We replaced the charged lysine residues in the artificial N termini with the m $\beta$ 3a<sub>12-21</sub> sequence (LQGRRRQGR) containing the R16–R18 and R21 residues. In contrast to the digestion of FIW-20Q-KKK-8Q- $\beta$ 2, the FIW-20Q- $\beta$ 3a<sub>12-21</sub>-8Q- $\beta$ 2 construct was found to be readily digested by 0.01 mg/ml trypsin (Fig. 10 D). This indicates that the intrinsic properties of the  $\beta$ 3a<sub>12-21</sub> segment are probably an important determinant of the rapid digestion of the  $\beta$ 3a N terminus compared with  $\beta$ 2. Furthermore, the result suggests that the KKK residues in the FIW-20Q-KKK-8Q- $\beta$ 2 construct probably do reside outside the antechamber, but that such residues are somehow less accessible to digestion by trypsin than in a freely mobile N terminus. We also tested two mutated versions of the FIW-20Q- $\beta$ 3a<sub>12-21</sub>-8Q- $\beta$ 2 construct: one with R16Q/R17Q and the other with three G/Q substitutions. Both exhibited digestion rates comparable to  $\beta$ 3a, suggesting that the R18R21 pair was sufficient to account for faster digestion, and that intrinsic flexibility conferred by glycine residues was not essential for the faster digestion.

We interpret these results as follows. Both  $\beta$ 2 and  $\beta$ 3a N termini likely bind in the antechamber, and segments

**Figure 10.** Impact of charge and the  $\beta$ 3a<sub>12-21</sub> segment inserted in artificial N-terminal linkers on trypsin digestion rates under closed-channel conditions. (A) The time course of trypsin-mediated removal of inactivation (0.1 mg/ml trypsin) is compared for constructs FIW-8Q-2K-20Q- $\beta$ 2 and FIW-20Q-2K-8Q- $\beta$ 2, in which the N terminus length is identical, but the basic residues are positioned at either 8 or 20 residues from the FIW motif. The digestion time course of wild-type  $\beta$ 2 is given by the red line. (B) The time courses of digestion for FIW-8Q-3K-20Q- $\beta$ 2 and FIW-20Q-3K-20Q- $\beta$ 2 are shown. (C) The time course of digestion for FIW-8Q-4K-20Q- $\beta$ 2 is compared with FIW-20Q-4K-8Q- $\beta$ 2. (D) The digestion time course with 0.01 mg/ml trypsin for a construct (FIW-20Q- $\beta$ 3a<sub>12-21</sub>-8Q- $\beta$ 2) in which segment  $\beta$ 3a<sub>12-21</sub> was inserted in an artificial N terminus is displayed ( $\tau_d = 28.9 \pm 4.0$  s;  $n = 2.3 \pm 0.5$ ) and compared with that of FIW-20Q-KKK-8Q with 0.1 mg/ml trypsin ( $\tau_d = 52.5 \pm 4.8$  s;  $n = 2.0 \pm 0.2$  for a different set of patches than in B). (E) The time course of digestion by 0.01 mg/ml trypsin is shown for two constructs in which the  $\beta$ 3a<sub>12-21</sub> segment (LQGRRRQGR) contained additional substitutions. In one, R16Q and R17Q resulted in an N terminus in which only R18 and R21 remained (LQGGQQRQGR;  $\tau_d = 45.4 \pm 3.7$  s;  $n = 2.1 \pm 0.2$ ). In the other, all glycines in the  $\beta$ 3a segment were mutated to Q ( $\tau_d = 40.3 \pm 5.2$  s;  $n = 1.8 \pm 0.3$ ).

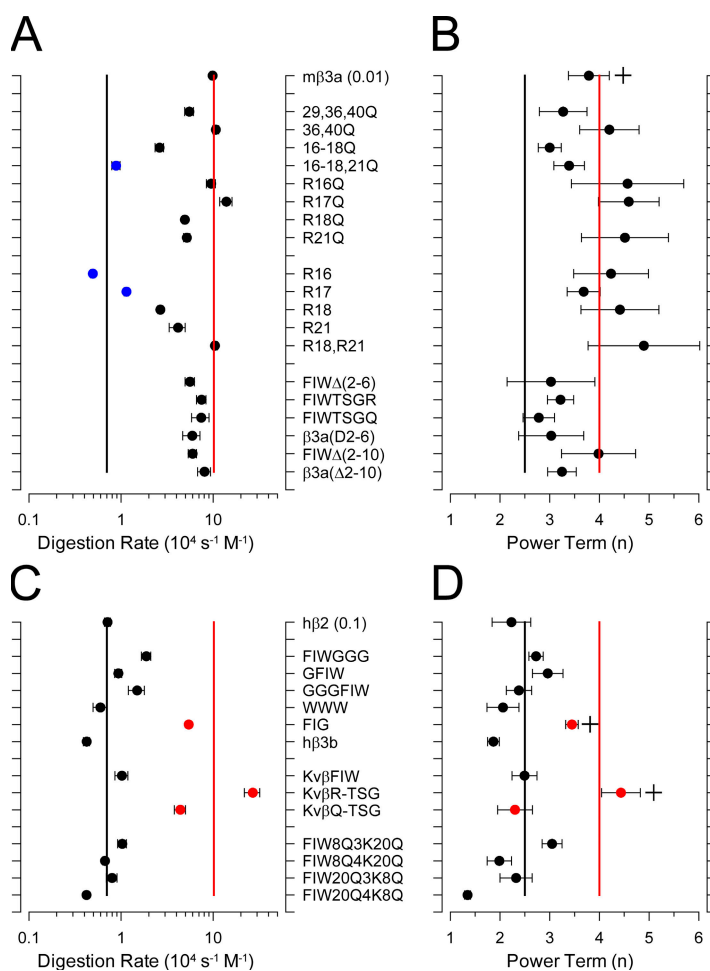

containing potentially digestible basic residues are likely to be positioned outside the antechamber when the N terminus is bound. We propose that the differential closed-channel protection exhibited for different N termini arises because of differential flexibility of the tethered N termini. Specifically, when a  $\beta 2$  N terminus is bound in the antechamber, the digestible basic residues of the  $\beta 2$  N terminus and some artificial N termini are less digestible than in a freely mobile N terminus. In contrast, when a  $\beta 3$  N terminus is bound in the antechamber, the segment of digestible residues in the  $\beta 3a$  N terminus retains sufficient flexibility to be digested at rates comparable to a freely mobile N terminus.

#### A Two-Site Protection Model Better Accounts for Some Aspects of Protection under Closed-Channel Conditions

The model given in Scheme 1 (Fig. 2 A) proposes that only a single N terminus can be protected by binding within the antechamber at a time. However, although values of  $n < 4$  require that fewer than four N termini can be protected at a time, might two or three N termini be protected at a time rather than just one? In fact, one aspect of our results is at variance with the quantitative predictions of the one-site model. Namely, for a wild-

type  $\beta 2$  construct that is digested with a power term of  $\sim 2.5$ , the one-site model predicts that, with complete removal of protection under closed-channel conditions ( $n = 4$ ), the digestion  $\tau_d$  should be faster by a factor of  $\sim 2$ – $5$  (Zhang et al., 2006). In contrast, for the W4G construct in which protection under closed-channel conditions is reduced (i.e.,  $n = \sim 3.4$ ), the digestion rate is about eightfold faster (Fig. 11). This suggests that, with complete removal of closed-channel-associated protection, the digestion process would be even faster, as was observed with  $\beta 3a$ .

The estimated values of  $n$  represent the upper limit for the number of domains that must be protected. For protection mediated by inactivation,  $n$  approaches 1.0, consistent with the idea that high affinity binding of a single domain is involved. A value of  $n$  of 2.5 under closed-channel conditions argues that fewer than three, but possibly either one or two domains may be protected. Because most  $\beta 2$  constructs exhibit  $n$  values less than 3.0 but greater than 2.0, the possibility of a three-site protection model seems unlikely, but a two-site model must be considered. To evaluate this issue, we used a simplified form of Scheme 1 in which channels are assumed to be at low open probability with no

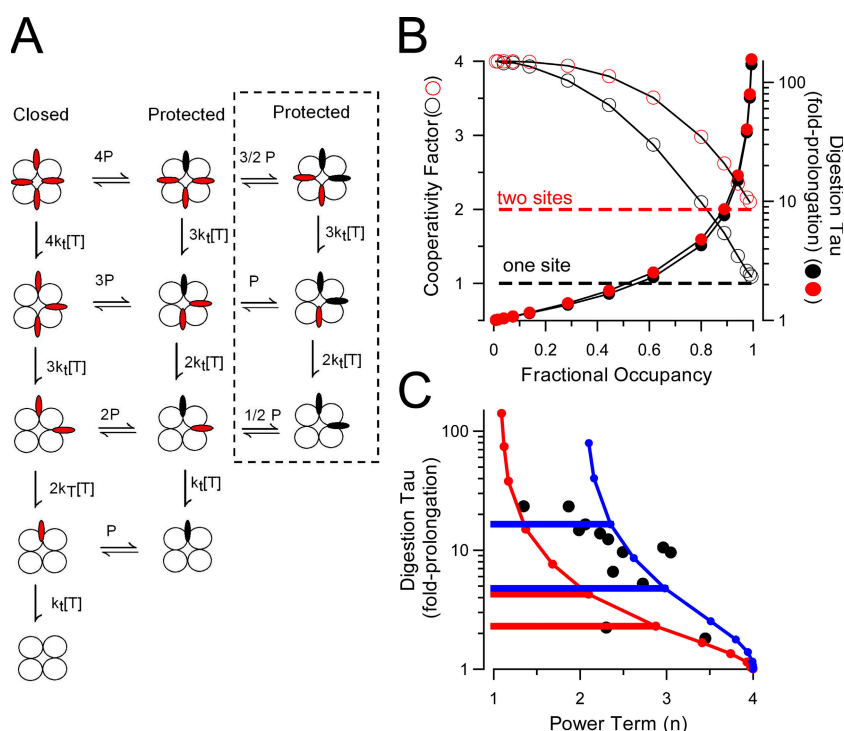

**Figure 11.** Summary of digestion rates and power terms for various constructs. (A) Apparent digestion rates were calculated for  $\beta 3a$ -derived constructs. For the calculation of effect rates, the trypsin molecular weight was assumed to be 24 kD. Red line indicates rate measured for wild-type  $\beta 3a$ , and the black line indicates the mean value for wild-type  $\beta 2$ . Blue symbols indicate those constructs with the most strongly slowed digestion for  $\beta 3a$ . (B) The fitted values for  $n$  are for  $\beta 3a$ -derived constructs shown to cluster around  $n = 4$ . Although there seems to be a trend for FIW-tagged constructs to have a lower value of  $n$ , ANOVA comparisons of  $n$  from sets of patches revealed no statistically significant difference between  $\beta 3a$  and any FIW-tagged construct. (C) Apparent digestion rates for  $\beta 2$ -related constructs are plotted, with the three with the largest increase in digestion rate highlighted in red. (D) Power terms for  $\beta 2$  constructs cluster around  $n = 2.5$ . Values for FIG (W4G;  $P = 0.00542$ ) and Kv $\beta$ TSGR ( $P = 7.01 \times 10^{-5}$ ) were found to be statistically different from wild-type  $\beta 2$  by ANOVA analysis, whereas comparison of  $n$  values for other constructs showed no difference with  $\beta 2$ . Power terms for  $\beta 2$  and  $\beta 3a$  were also significantly different ( $P = 0.00542$ ).

inactivation (Fig. 12 A). Open and inactivated states are removed from the model with essentially no effect on the predicted time course of digestion under closed-channel conditions. We extended the single-site model in Scheme 1 to include the possibility that a second N terminus can also be protected from digestion by trypsin (Fig. 12 A). For both the one- and two-site formulations, we simulated the predicted digestion time course while varying the affinity of the protection site(s). This allowed determination of  $\tau_d$  and  $n$  for different fractional occupancies of the protection sites (Fig. 12 B). For the one-site model, fractional occupancy of 1.0 corresponds to 100% occupancy of the single protection site by a single N terminus, whereas for the two-site model, fractional occupancy of 1.0 corresponds to 100% occupancy of two protection sites. Thus, for the one-site model, at high fractional occupancy, three N termini remain accessible to trypsin at most times, whereas for the two-site model, two N termini remain accessible. In both models, appreciable effects on digestion  $\tau_d$  and  $n$  were predicted to occur only at fractional occupancies above  $\sim 0.75$ . The relationship between the predicted prolongation of  $\tau_d$  and  $n$  (Fig. 12 C) for each model may provide a way to distinguish between them. For the one-site model, for  $n$  between 2 and 3,

the digestion time constant is predicted to be only approximately two- to fivefold slower than that which would be observed when there is no closed-channel protection. In contrast, for the two-site model, for  $n$  between 2 and 3, the digestion  $\tau_d$  is predicted to be  $\sim 5$ – $20$ -fold slower than that expected for no closed-channel protection.

We observed that the W4G- $\beta 2$  mutation exhibited a digestion rate (Figs. 3 and 11) that was approximately eightfold that of the wild-type  $\beta 2$  construct, whereas the power term,  $n$ , for W4G- $\beta 2$  was  $\sim 3.4$ . With mutated  $\beta 3a$  N termini containing only two digestible basic residues, the effective digestion rates were about almost 20-fold that of wild-type  $\beta 2$ , with an  $n$  value close to 4.0. These results with W4G- $\beta 2$  and  $\beta 3a$  constructs set an upper limit on the potential increase in digestion rate that can occur in the absence of any closed-channel protection, and fold increase in rates is much greater than would be expected based on a strictly single-site protection model. Using the  $\beta 3a$  digestion rate as that characteristic of an N terminus with two attackable basic residues, but with no closed-channel protection, we calculated the fold-prolongation for various mutated  $\beta 2$  N termini (as listed in Fig. 11). These prolongations relative to the fitted estimates of  $n$ , when compared (Fig. 12 C) to the

**Figure 12.** A model in which two N termini can dwell within the antechamber at a time may better account for the data. (A) The two left-hand columns of states correspond to Scheme 1 under conditions of low  $P_o$  and no inactivation and, therefore, approximate closed-channel conditions for a model in which one N terminus can occupy the antechamber at a time. The additional states highlighted in the dotted rectangle propose that an additional N terminus can also bind, presumably in the antechamber, thereby being protected from digestion by trypsin. Red and black ovals correspond to unprotected and protected N termini, respectively. (B) Both one- and two-site models were used to simulate the trypsin-mediated removal of inactivation over a range of values of  $P$ , the binding constant for the site producing closed-channel-associated protection. Fractional occupancy was calculated as:  $P_a = p_f / (p_f + p_r)$ , where  $p_f$  and  $p_r$  are defined as the rates of binding and unbinding of an N terminus in the antechamber (Table II). Both models predict a similar prolongation of  $\tau_d$  (filled circles) with occupancy within the antechamber, whereas the two differ in regards to the limiting power term at high fractional occupancies (open circles). Note that, for the

one-site model, the relationship between fractional occupancy, prolongation of  $\tau_d$ , and  $n$  were plotted incorrectly in our previous report (Zhang et al., 2006), as described in Materials and methods. (C) The prolongation of  $\tau_d$  is plotted as a function of the power term for the one-site (red) and two-site (blue) models. The horizontal lines mark the range of prolongations, relative to the case for  $n = 4$ , expected for power terms in the range of 2 to 3. The filled black circles correspond to measurements of  $n$  and calculations of prolongation of  $\tau_d$  for wild-type  $\beta 2$  and mutated  $\beta 2$  constructs, assuming that the digestion rate of  $\beta 3a$  most closely reflects digestion of an N terminus without protection in the antechamber. If the rate of digestion of the W4G construct is used as the  $\tau_d(\text{min})$ , the points are shifted leftward, but still favor the idea that two sites are involved in closed-channel-associated protection.

predictions of the one- and two-site models, suggest that a two-site model may better account for the experimentally observed range of values for  $\tau_d$  and  $n$ .

## DISCUSSION

Several ion channels contain cytosolic domains that are appended to the membrane-embedded, pore-forming domains and play important roles in regulation of channel gating (Gulbis et al., 2000; Schumacher et al., 2001; Jiang et al., 2002; Xia et al., 2004). Both for Kv channels (Gulbis et al., 2000; Kobertz et al., 2000) and for BK channels (Zhang et al., 2006), it has been proposed that, because of the appended cytosolic structure “hanging” from the pore-forming domain, mobile cytosolic inactivation domains access their positions of inactivation laterally by passing through side portals between the membrane and cytosolic domains (e.g., Fig. 1 A). Our previous study had proposed that, under closed-channel conditions and even more so under inactivating conditions,  $\beta 2$  N termini were protected from digestion by trypsin (Zhang et al., 2006). These observations led to a model in which inactivation domains could be protected from trypsin digestion by occupancy within a protected volume between the pore domain and cytosolic domain. The specific lengths of artificial N termini that were either unprotected or protected from trypsin digestion during inactivation also allowed some suggestions regarding the dimensions of the protected space.

Here, we have evaluated several predictions of this model to define more clearly whether protection of N termini occurs under conditions in which channels are predominantly closed, what the stoichiometry of that protection may be, and whether these properties are generalizable to a variety of different N termini. The results included three observations that provide strong support for the idea that, under closed-channel conditions,  $\beta 2$  N termini can be protected from trypsin digestion, and that the sites involved in closed-channel-associated protection are distinct from the site involved in inactivation-associated protection against digestion. First, closed-channel-associated protection predicts that reduction of affinity of the N termini for the antechamber site of protection will speed up digestion. This was observed in some constructs. Second, the proposal predicts that disruption of closed-channel-associated protection will result in a steeper power term in the digestion time course. This is also observed with particular constructs. Third, the idea that closed-channel-associated protection and inactivation-associated protection involve distinct sites of binding of a  $\beta$  subunit N terminus was supported by two observations: first, that bbTBA disrupted inactivation-associated protection but not closed-channel-associated protection, and, second, that different N-terminal constructs had differential effects on closed-channel-associated protec-

tion compared with inactivation-associated protection. On balance, then, the results provide strong support for the general model outlined at the outset. Finally, analysis of the variation of digestion  $\tau_d$  with estimates of  $n$  allowed the proposal that protection against digestion under closed-channel conditions may involve similar binding of up to two N-terminal domains.

A key element in the argument that, under closed-channel conditions, N termini can be protected from digestion by trypsin was the observation that the power term,  $n$ , in fits of Eq. 1 to the digestion time course exhibited values in the range of 2.0 to 3.0 (Zhang et al., 2006). This required a model in which N termini are not equally digestible at all times by trypsin, and we have shown that the power term,  $n$ , can approach 4 with manipulations that might be expected to disrupt closed-channel-associated protection. Because the digestion time course is defined by a rather limited set of time points, we have been concerned about the robustness of the estimates of  $n$ . However, several factors provide confidence that the differences in  $n$  reported here do reflect underlying differences in the protection mechanism. First, for cases in which a  $\beta 2$  N terminus is made more readily digestible, an increase in  $n$  is also observed. However, simply changing the  $\beta 2$  digestion rate by varying [trypsin] has no effect on estimates of  $n$  (Zhang et al., 2006). Second, for h $\beta 3a$  for which closed-channel-associated protection does not appear to occur and the power term approaches 3.6, slowing digestion by removing key basic residues does not alter the power term (Fig. 11 and Figs. S1 and S2). Thus, values of  $n$  approaching 4 are consistently observed for  $\beta 3a$ -derived constructs. Third, the differences among estimates of  $n$  between pairs of constructs showed statistically significant differences (Fig. 11), e.g., between  $\beta 2$  and  $\beta 2$ -W4G. These considerations provide confidence that the estimates of  $n$  are indicative of the properties of closed-channel-associated protection for a given construct.

### What Is the Mechanistic Basis for Closed-Channel-associated Protection?

The simple fact that the stoichiometry for closed-channel-associated protection is  $<4$  requires that binding by some N termini excludes other N termini from simultaneously occupying a similar site. For a one-site antechamber model, we had supposed that the basic physical dimensions of the  $\beta 2$  N terminus and likely dimensions of the channel antechamber (e.g., Fig. 1 A) might prevent other N termini from a similar position of protection (Zhang et al., 2006). There is no information concerning how much of the antechamber might be occupied by an individual N terminus when it is in a position of protection and, in fact, our results seem more consistent with the idea that two N termini may simultaneously occupy positions of protection within the antechamber while excluding access of the other

two N termini to similar positions. Given the limited dimensions of the antechamber and the size of the  $\beta 2$  N terminus (Jiang et al., 2002; Zhang et al., 2006), the idea that only one or two N termini may occupy this space at a time seems plausible. It is unlikely that this binding is somewhere besides the antechamber, because the simplest way of achieving a stoichiometry of  $<4$  requires competition for sites accessible to all N termini. It should also be realized that the observed stoichiometry arises not because there are two antechamber binding sites, but rather because once two sites are occupied, no more N termini can reach any other sites.

Once an N terminus binds within the antechamber in a closed channel, how does this reduce digestion by trypsin? We considered four possible N-terminal configurations that might impact on digestion (Fig. 9 E). The most basic protection mechanism would be that, when an N terminus is bound within the antechamber, digestible basic residues are also within the antechamber (Fig. 9 E, Case 1). This mechanism likely applies to inactivation-associated protection because in artificial N termini, basic residues within 11 positions of the terminal FIW epitope are protected from digestion, whereas positions  $>11$  amino acids from the FIW abolish inactivation-associated protection (Zhang et al., 2006). However, for closed-channel-associated protection, we do not know whether the digestible residues in either  $\beta 2$  or  $\beta 3a$  are completely hidden within the antechamber when the N terminus is bound. As illustrated by Case 2 (Fig. 9 E), when an N terminus is bound, it may be that the flexibility and motion in the linker are restricted or a secondary structure is enforced, such that even if the basic residues are not within the antechamber, they may not be readily digestible by trypsin. In contrast, for other N termini, binding in the antechamber may fail to place structural constraints on the digestible basic residues (Fig. 9 E, Case 3), such that protection in closed channels does not occur. Finally, some N termini may fail to bind appreciably in the antechamber (Fig. 9 E, Case 4).

Through the swapping of segments between  $\beta 2$  and  $\beta 3$  N termini and examination of the properties of digestion of artificial N termini, our results favor the view that, when N termini are protected from digestion under closed-channel conditions, digestible basic residues are unlikely to be hidden within the antechamber itself. Rather, we propose that the faster digestion of the  $\beta 3a$  N terminus compared with  $\beta 2$  arises because the segment containing the digestible R18 and R21 residues in  $\beta 3a$  exhibits marked flexibility, even when the hydrophobic end of the  $\beta 3a$  N terminus is bound in the antechamber. This flexibility around the basic residues (Case 3) thereby permits digestion by trypsin in a fashion similar to an N terminus entirely outside the antechamber (Case 4). In contrast, we propose that the  $\beta 2$  N terminus, when bound in the antechamber, places constraints on the R8 and

R19  $\beta 2$  residues, making them less accessible to digestion by trypsin than if the N terminus is freely mobile.

This view that different N termini, when bound in the antechamber, may have different rates of digestion because of flexibility of the region around the basic residues may also explain results with artificial  $\beta 2$  N-terminal linkers. Specifically, to explain the similarity of digestion rates of artificial  $\beta 2$  N termini and wild-type  $\beta 2$ , we propose that, when the FIW motif is tethered to a site within the antechamber, the mobility of the linker in the artificial N terminus is sufficiently constrained in motion so that it provides some protection against attack by trypsin. This idea was given further support by the demonstration that insertion of the  $\beta 3a$  segment of basic residues into an artificial N terminus resulted in digestion rates more comparable to  $\beta 3a$  than  $\beta 2$ , suggesting that this particular  $\beta 3a$  segment has more flexibility than the lysine residues embedded in the polyglutamine chain. This idea that the polyglutamine N termini may confer some constraint on accessibility of trypsin to the basic residues seems surprising given that several studies suggest that polyglutamine chains are largely random coils (Wang et al., 2006; Vitalis et al., 2007), only transiently adopting shorter, more ordered features (Leitgeb et al., 2007). Intrinsically, we would have expected that such chains should not adopt structures that might preclude attack by trypsin on basic residues. However, our observations here clearly raise the possibility that the polyglutamine chains we have used may not behave like random coils or may at least transiently adopt some sort of constrained structure that makes them less amenable to attack than the native  $\beta 3a$  N terminus. Potentially, the method used here could be exploited to undertake a quantitative examination of chain flexibilities of different composition, with a variety of consensus substrate sequences.

### Summary

The results here support a model in which  $\beta 2$  and  $\beta 3a$  N-terminal inactivation domains can transiently bind to sites that confer protection against digestion by trypsin. Two types of protection can occur. When an N terminus produces inactivation, that N terminus appears to be absolutely protected from digestion by trypsin. However, in closed channels, N termini can also transiently bind to a site distinct from the site involved in inactivation-associated protection. The data are most consistent with the idea that up to two N termini can be simultaneously protected from digestion by trypsin. Because protection in closed channels involves fewer than four N termini, the site of binding of the N terminus is most likely within the antechamber of the channel. The protection against digestion by trypsin that occurs in closed channels appears to arise, not because the basic residues are shielded within the antechamber, but rather because basic residues in the bound N terminus are less accessible to trypsin digestion than basic residues in a freely mobile N terminus.
