Pheromones are substances released from animals that, when detected by the vomeronasal organ of other individuals of the same species, affect their physiology and behavior. Pheromone binding to receptors on microvilli on the dendritic knobs of vomeronasal sensory neurons activates a second messenger cascade to produce an increase in intracellular Ca^{2+} concentration. Here, we used whole-cell and inside-out patch-clamp analysis to provide a functional characterization of currents activated by Ca^{2+} in isolated mouse vomeronasal sensory neurons in the absence of intracellular K^+ . In whole-cell recordings, the average current in $1.5 \mu\text{M}$ Ca^{2+} and symmetrical Cl^- was -382 pA at -100 mV . Ion substitution experiments and partial blockade by commonly used Cl^- channel blockers indicated that Ca^{2+} activates mainly anionic currents in these neurons. Recordings from inside-out patches from dendritic knobs of mouse vomeronasal sensory neurons confirmed the presence of Ca^{2+} -activated Cl^- channels in the knobs and/or microvilli. We compared the electrophysiological properties of the native currents with those mediated by heterologously expressed TMEM16A/anoctamin1 or TMEM16B/anoctamin2 Ca^{2+} -activated Cl^- channels, which are coexpressed in microvilli of mouse vomeronasal sensory neurons, and found a closer resemblance to those of TMEM16A. We used the Cre-loxP system to selectively knock out TMEM16A in cells expressing the olfactory marker protein, which is found in mature vomeronasal sensory neurons. Immunohistochemistry confirmed the specific ablation of TMEM16A in vomeronasal neurons. Ca^{2+} -activated currents were abolished in vomeronasal sensory neurons of TMEM16A conditional knockout mice, demonstrating that TMEM16A is an essential component of Ca^{2+} -activated Cl^- currents in mouse vomeronasal sensory neurons.

INTRODUCTION

Chemosensation is used by animals to obtain information from the environment and to regulate their behavior. In most mammals, both the main olfactory epithelium and the vomeronasal epithelium are involved in chemodetection (Brennan, 2009; Tirindelli et al., 2009; Touhara and Vossahl, 2009). Sensory neurons in these epithelia detect chemicals and, through different second messenger-mediated transduction pathways, generate action potentials that are transmitted to different regions of olfactory bulbs. In vomeronasal sensory neurons, the binding of chemicals with vomeronasal receptors occurs in the microvilli, at the apical region of the neuron's dendrite. In rodents, these neurons express one or a few members of three families of G protein-coupled receptors: V1Rs, V2Rs, and formyl peptide receptors (FPRs) (Dulac and Axel, 1995; Herrada and Dulac, 1997; Matsunami

and Buck, 1997; Ryba and Tirindelli, 1997; Martini et al., 2001; Liberles et al., 2009; Rivière et al., 2009; Francia et al., 2014). The binding of molecules to vomeronasal receptors activates a phospholipase C pathway, which leads to the influx of Na^+ and Ca^{2+} ions mainly through the transient receptor potential canonical 2 (TRPC2) channel present in the microvilli (Liman et al., 1999; Zufall et al., 2005; Munger et al., 2009), and/or to Ca^{2+} release from intracellular stores (Kim et al., 2011).

The vomeronasal organ (VNO) plays an important role in the detection of pheromones. Stimulation of the VNO with urine, which contains a rich blend of pheromones, or with individual pheromones, produces a transient increase in intracellular Ca^{2+} concentration in vomeronasal sensory neurons (Holy et al., 2000; Leinders-Zufall et al., 2000, 2004, 2009; Chamero et al., 2007, 2011; Haga et al., 2010; Kim et al., 2011; Celsi et al., 2012). The intracellular Ca^{2+} increase has several physiological effects, including activation of ion channels (Liman, 2003; Spehr et al., 2009; Yang and Delay, 2010;

Kim et al., 2011, 2012; Dibattista et al., 2012) and modulation, through binding to calmodulin, of sensory adaptation (Spehr et al., 2009).

Previous studies in vomeronasal sensory neurons identified the presence of Ca^{2+} -activated currents; some studies found Ca^{2+} -activated nonselective cation currents (Liman, 2003; Spehr et al., 2009), whereas other studies found Ca^{2+} -activated Cl^- currents (Yang and Delay, 2010; Kim et al., 2011; Dibattista et al., 2012). In hamster vomeronasal sensory neurons, Liman (2003) measured Ca^{2+} -activated nonselective cation currents with half-activation occurring at 0.51 mM Ca^{2+} at -80 mV. In mouse vomeronasal sensory neurons, Spehr et al. (2009) showed that 50 μM Ca^{2+} activated nonselective cation currents in patches from dendritic knobs from a small population of neurons (12.5%; 7 out of 56). Other recent studies showed that Ca^{2+} -activated Cl^- channels contribute to the response of mouse vomeronasal neurons to urine (Yang and Delay, 2010; Kim et al., 2011). Furthermore, the presence of Ca^{2+} -activated Cl^- channels in the apical portion of vomeronasal sensory neurons was confirmed by local photorelease of Ca^{2+} from caged Ca^{2+} (Dibattista et al., 2012) and by the expression of TMEM16A and TMEM16B (Dibattista et al., 2012), two proteins forming Ca^{2+} -activated Cl^- channels (Caputo et al., 2008; Schroeder et al., 2008; Yang et al., 2008; Pifferi et al., 2009a; Stephan et al., 2009; Stöhr et al., 2009; Scudieri et al., 2012; Pedemonte and Galletta, 2014). The aim of this study was to further characterize the ionic nature (in the absence of intracellular K^+ to avoid the contribution of Ca^{2+} -activated K^+ currents) of Ca^{2+} -activated currents in mouse vomeronasal sensory neurons and to identify the molecular identity of the channels mediating these currents. We performed recordings both in whole-cell and in inside-out patches from dendritic knobs/microvilli of mouse vomeronasal neurons, and we measured only Ca^{2+} -activated Cl^- currents with biophysical properties more similar to those of TMEM16A than of TMEM16B. To investigate the role of TMEM16A in vomeronasal neurons, we generated conditional knockout mice for TMEM16A, as the constitutive TMEM16A knockout mice die soon after birth (Rock et al., 2008). Our results demonstrate the presence of Ca^{2+} -activated Cl^- currents in the apical portion of vomeronasal sensory neurons of WT mice, confirm that TMEM16A is expressed in mature neurons, and show that TMEM16A is a necessary component of Ca^{2+} -activated Cl^- channels in mouse vomeronasal sensory neurons.

MATERIALS AND METHODS

Animals

Mice were handled in accordance with the Italian Guidelines for the Use of Laboratory Animals (Decreto Legislativo 27/01/1992, no. 116) and European Union guidelines on animal research

(no. 86/609/EEC). 2–3-mo-old mice were anaesthetized by CO_2 inhalation and decapitated before VNO removal.

To obtain mice in which TMEM16A expression was specifically eliminated in mature vomeronasal sensory neurons, we crossed floxed TMEM16A^{fl/fl} mice, whose generation has been described in detail (Faria et al., 2014; Schreiber et al., 2014), with mice expressing *Cre* recombinase under the control of the olfactory marker protein (*OMP*) promoter (*OMP-Cre* mice; Li et al., 2004; provided by P. Mombaerts, Max Planck Institute of Biophysics, Frankfurt, Germany). Our conditional TMEM16A knockout mice (TMEM16A cKO) were homozygous for the floxed TMEM16A alleles and heterozygous for *Cre* and *OMP*. C57BL/6 or TMEM16A^{fl/fl} mice were used as controls. In the following, WT mice correspond to C57BL/6 mice.

Dissociation of mouse vomeronasal sensory neurons

The vomer capsule containing the VNO was removed as described previously (Liman and Corey, 1996; Dean et al., 2004; Shimazaki et al., 2006; Arnson et al., 2010). Vomeronasal sensory neurons were dissociated from the VNO with the enzymatic-mechanical dissociation protocol described in Dibattista et al. (2008, 2012), or with the following slight modifications. In brief, the removed vomer capsule was put into a Petri dish containing divalent-free PBS (Sigma-Aldrich) solution where the VNO was extracted and transferred to a tube containing PBS with 1 mg/ml collagenase (type A), incubated at 37°C for 20 min, and transferred twice to Ringer's solution with 5% fetal bovine serum for 5 min. The tissue was then cut into small pieces with tiny scissors and gently triturated with a fire-polished Pasteur pipette. Neurons were plated on Petri dishes (WPI) coated with poly-L-lysine and concanavalin A (type V; Sigma-Aldrich) and stored at 4°C.

Patch-clamp recordings and ionic solutions

Vomeronasal sensory neurons were viewed using an inverted microscope (IMT-2 or IX70; Olympus) with 20× or 40× objectives and identified by their bipolar shape, as illustrated in Fig. 1 of Dean et al. (2004). Patch pipettes, pulled from borosilicate capillaries (WPI) with a PC-10 puller (Narishige), had a resistance of ~ 3 –6 M Ω for whole-cell and 6–8 M Ω for excised patch recordings. Currents were recorded with an Axopatch 1D or 200B amplifier controlled by Clampex 9 or 10 via a Digidata 1332A or 1440 (Molecular Devices). Data were low-pass filtered at 2 or 5 kHz and sampled at 10 kHz. Experiments were performed at room temperature (20–25°C).

For whole-cell recordings, the standard extracellular mammalian Ringer's solution contained (mM): 140 NaCl, 5 KCl, 2 CaCl_2 , 1 MgCl_2 , 10 HEPES, 10 glucose, and 1 sodium pyruvate, pH 7.4. The intracellular solution filling the patch pipette contained (mM): 140 CsCl, 10 HEPES, and 10 HEDTA, adjusted to pH 7.2 with CsOH, and no added Ca^{2+} for the nominally 0- Ca^{2+} solution, or various added Ca^{2+} concentrations, as calculated with the program WinMAXC (C. Patton, Stanford University, Stanford, CA), to obtain free Ca^{2+} in the range between 0.5 and 13 μM (Patton et al., 2004), as described previously (Pifferi et al., 2006, 2009b). The composition of the intracellular solutions containing 2 mM Ca^{2+} was (mM) 140 CsCl, 10 HEPES, 2 CaCl_2 or 145 NaCl, 10 HEPES, and 2 CaCl_2 , as in Liman (2003). No significant difference was observed among currents activated by the two solutions containing 2 mM Ca^{2+} . For ionic selectivity experiments, NaCl in the extracellular mammalian Ringer's solution was replaced with equimolar choline chloride, Na-gluconate, or NaSCN. Niflumic acid (NFA), $\text{CaCC}_{\text{inh}}\text{A01}$ (Tocris Bioscience), and anthracene-9-carboxylic acid (A9C) were prepared in DMSO as stock solutions at 200 mM, 20 mM, or 1 M, respectively, and diluted to the final concentrations in Ringer's solution. A gravity perfusion system was used to exchange solutions.

In most whole-cell recordings, we applied voltage steps from a holding potential of 0 mV ranging from -100 to 100 (or 160 mV), followed by a step to -100 mV. A single-exponential function was fitted to instantaneous tail currents to extrapolate the current value at the beginning of the step to -100 mV.

For inside-out recordings, the solution in the patch pipette contained (mM): 140 NaCl, 10 HEDTA, and 10 HEPES, pH 7.2. The bathing solution at the intracellular side of the patch contained (mM): 140 NaCl, 5 EGTA or 10 HEDTA, and 10 HEPES, pH 7.2, and no added Ca^{2+} for the nominally 0-Ca^{2+} solution, or various added Ca^{2+} concentrations, as calculated with the program WinMAXC (C. Patton, Stanford University, Stanford, CA), to obtain free Ca^{2+} in the range between 0.18 and $100\text{ }\mu\text{M}$ (Patton et al., 2004).

Rapid solution exchange in inside-out patches was obtained with the perfusion Fast-Step (SF-77B; Warner Instruments). For I-V relations of Ca^{2+} -activated currents, a double voltage ramp from -100 to 100 mV and back to -100 mV was applied at 1 mV/ms . The two I-V relations were averaged, and leak currents measured with the same ramp protocol in Ca^{2+} -free solutions were subtracted. For dose-response experiments, a patch was exposed for 1 s to solutions with increasing Ca^{2+} concentration.

The bath was grounded through a 3-M KCl agar bridge connected to a Ag/AgCl reference electrode. Liquid junction potentials were calculated using Clampex's Junction Potential Calculator (Molecular Devices), based on the JPCalc program developed by Barry (1994), and applied voltages were corrected offline for the calculated values.

Chemicals, unless otherwise stated, were purchased from Sigma-Aldrich.

Analysis of electrophysiological data

IGOR Pro software (WaveMetrics) was used for data analysis and figures. Data are presented as mean \pm SEM and the number of neurons (n). Because most of the data were not normally distributed (Shapiro-Wilk test), statistical significance was determined using Wilcoxon Signed Rank test or Kruskal-Wallis test. When a statistically significant difference was determined with Kruskal-Wallis analysis, Dunn-Hollander-Wolfe test was done to evaluate which data groups showed significant differences. P-values of <0.05 were considered statistically significant. For the sake of clarity, capacitive transients were trimmed in some traces.

Immunohistochemistry

VNO sections and immunohistochemistry were obtained as described previously (Dibattista et al., 2012). The following primary antibodies were used: rabbit anti-TMEM16A (1:50; Abcam), goat anti-TMEM16A (1:50; Santa Cruz Biotechnology, Inc.), rabbit anti-TMEM16B (1:100; Santa Cruz Biotechnology, Inc.), and goat anti-TRPC2 (1:50; Santa Cruz Biotechnology, Inc.). The following secondary antibodies obtained from Invitrogen were used: donkey anti-rabbit Alexa Fluor 488 (1:500) and donkey anti-goat Alexa Fluor 594 (1:500). Immunoreactivity was visualized with a confocal microscope (TCS SP2; Leica). Images were acquired using Leica software (at $1,024 \times 1,024$ -pixel resolution) and were not modified other than to balance brightness and contrast. Nuclei were stained by DAPI, and signals were enhanced for better visualization of the vomeronasal epithelium. Control experiments without the primary antibodies gave no signal.

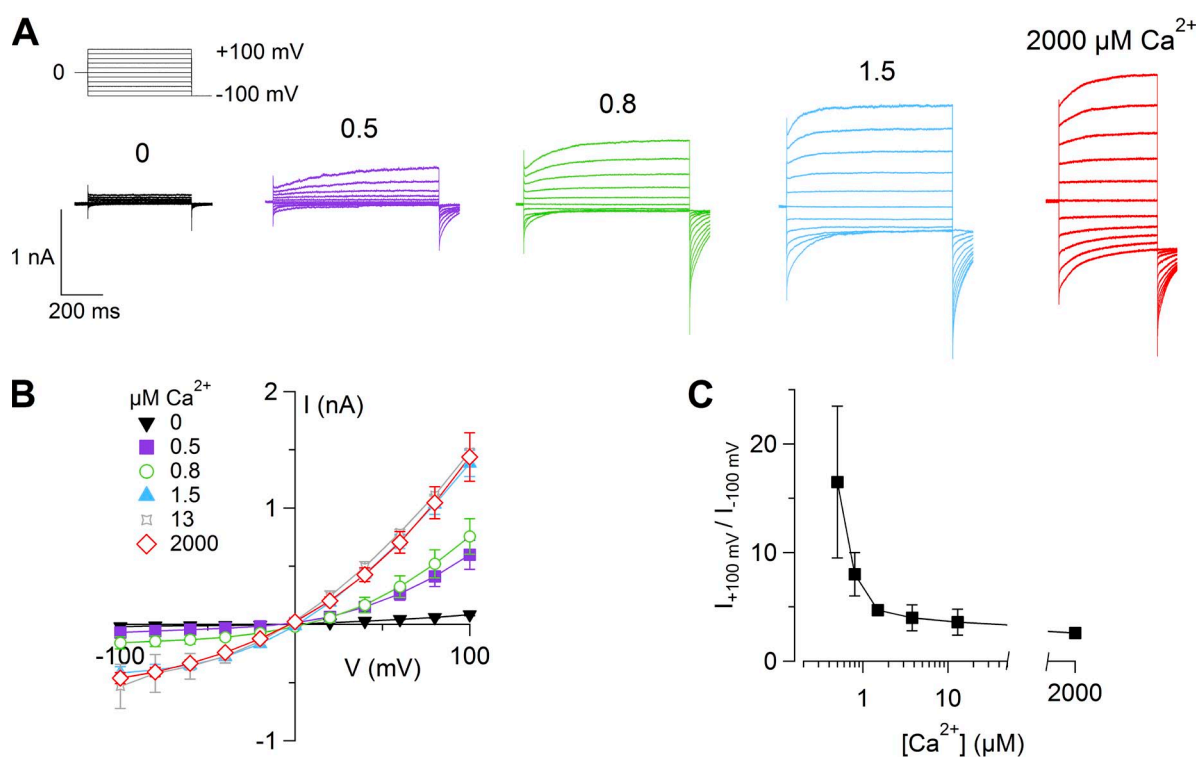

Figure 1. Ca^{2+} -activated currents in mouse vomeronasal sensory neurons. (A) Representative whole-cell currents recorded from different neurons with a pipette solution containing the indicated $[\text{Ca}^{2+}]_i$ (for the trace in 2 mM Ca^{2+} , the intracellular solution contained 140 mM NaCl). The holding voltage was 0 mV and voltage steps from -100 to 100 mV with 20-mV increments, followed by a step to -100 mV, were applied as indicated in the top part of the panel. (B) Average steady-state I-V relationships from several neurons at the indicated $[\text{Ca}^{2+}]_i$ ($n = 3\text{--}28$). (C) Average ratios between steady-state currents measured at 100 and -100 mV at various $[\text{Ca}^{2+}]_i$ ($n = 3\text{--}28$). Data in B and C are represented as mean \pm SEM.

RESULTS

Ca²⁺-activated Cl⁻ currents in isolated mouse vomeronasal sensory neurons

We first studied Ca²⁺-activated currents in isolated mouse vomeronasal sensory neurons using the whole-cell voltage-clamp configuration with intracellular solutions containing different amounts of free [Ca²⁺]_i, ranging from nominally 0 Ca²⁺ up to 2 mM Ca²⁺. To avoid contributions from Ca²⁺-activated K⁺ currents, the intracellular monovalent cation was Cs⁺ (or Na⁺ in some experiments in the presence of 2 mM Ca²⁺).

Fig. 1 A shows currents activated by voltage steps between -100 and 100 mV from a holding voltage of 0 mV. The average current in the presence of nominally 0 Ca²⁺ was 82 ± 9 pA at 100 mV and -20 ± 7 pA at -100 mV (*n* = 6). When neurons were dialyzed with a solution containing 0.5 μM Ca²⁺, large currents were recorded in several neurons at positive voltages, with an average value at steady state of 545 ± 96 pA (range of 133 to 1,060 pA) at 100 mV, and -50 ± 17 pA (range of -21 to -163 pA) at -100 mV (*n* = 10). Further increases in [Ca²⁺]_i produced currents of higher amplitudes, reaching the average of 1,503 ± 146 pA (range of 615 to 3,530 pA) at 100 mV (*n* = 28) in the presence of 1.5 μM Ca²⁺. The average current amplitude did not further increase for [Ca²⁺]_i up to 2 mM.

The I-V relations measured at steady state were outwardly rectifying (Fig. 1, B and C), and the rectification index, calculated as the ratio between current at 100 and -100 mV, decreased from 16 ± 7 at 0.5 μM Ca²⁺ to 5.5 ± 0.6 at 1.5 μM Ca²⁺ and 3.2 ± 0.3 at 2 mM Ca²⁺, showing that the I-V relation is Ca²⁺ dependent and becomes more linear as [Ca²⁺]_i increases.

All together, we tested 178 neurons with various [Ca²⁺]_i and found that 70% of the neurons (124 out of 178) had a Ca²⁺-activated current. The remaining 30% of the neurons (54 out of 178) did not have Ca²⁺-activated currents but showed transient voltage-gated inward currents (likely Na⁺ currents) in response to a depolarizing step to 0 mV from a holding potential of -100 mV.

In the presence of Ca²⁺, voltage steps induced currents composed of an instantaneous component and a time-dependent relaxation (Figs. 1 A and 2, A and B). The instantaneous component is related to channels open at the holding potential of 0 mV, whereas the time-dependent component is the result of the activation of the channel at a given voltage step, indicating that these channels are regulated both by Ca²⁺ and by voltage.

The time-dependent component was fit by a single-exponential function to calculate the time constant of activation, τ_{act} . At 100 mV, τ_{act} in the presence of 0.5 μM Ca²⁺ was 235 ± 29 ms (*n* = 7), decreased to 156 ± 15 ms (*n* = 8) at 0.8 μM Ca²⁺, and to 46 ± 6 ms (*n* = 6) at 1.5 μM Ca²⁺ (Fig. 2, A-C). At all the tested intracellular Ca²⁺ concentrations, the activation kinetics did not show

voltage dependence in the range between 80 and 160 mV (not depicted).

We examined the deactivation kinetics by measuring the decay of the instantaneous current after a step from 100 to -100 mV (Fig. 2, A, B, and D). The best fit of the current decay was obtained with two exponential functions with average $\tau_{deact1} = 4.1 \pm 0.7$ ms and $\tau_{deact2} = 50 \pm 4$ ms (*n* = 7) at 0.5 μM Ca²⁺. Increasing [Ca²⁺]_i to 1.5 μM produced a slower decay of the current, with average $\tau_{deact1} = 7 \pm 1$ ms and $\tau_{deact2} = 100 \pm 11$ ms (*n* = 5).

These results show that an increase in [Ca²⁺]_i accelerates activation and slows deactivation.

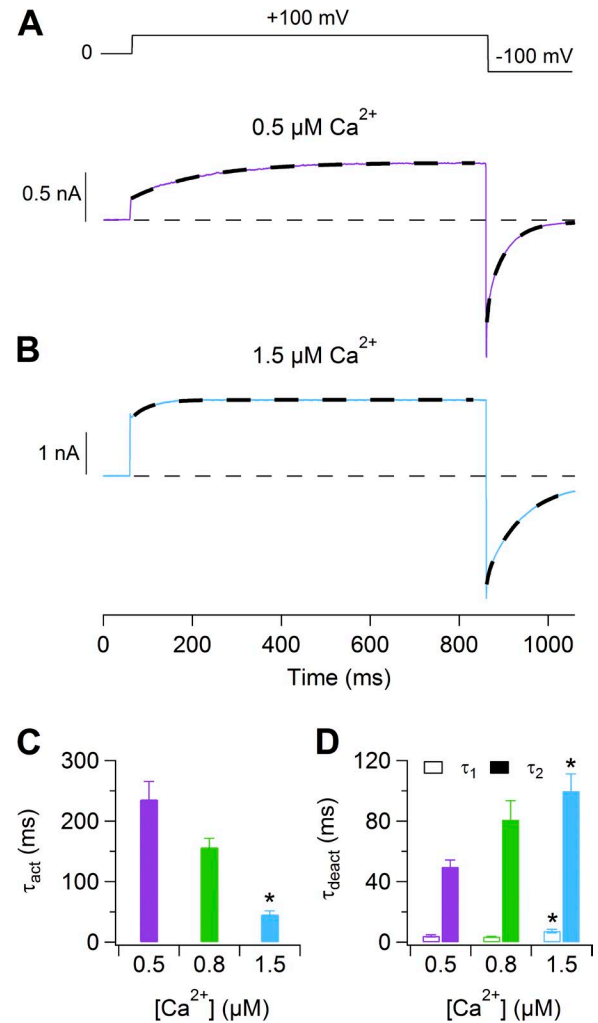

Figure 2. Activation and deactivation kinetics of Ca²⁺-activated currents. (A and B) Representative currents with 0.5 and 1.5 μM [Ca²⁺]_i, respectively. The voltage was stepped from 0 to 100 mV and then to -100 mV. Dashed lines are the fit of activation or deactivation time constants obtained, respectively, with a single- or double-exponential function. (C and D) Average activation (from 0 to 100 mV) or deactivation (from 100 to -100 mV) time constants at the indicated [Ca²⁺]_i (*n* = 5–7). Data in C and D are represented as mean ± SEM (*, *P* < 0.05; Dunn–Hollander–Wolfe test after Kruskal–Wallis analysis between 0.5 and 1.5 μM).

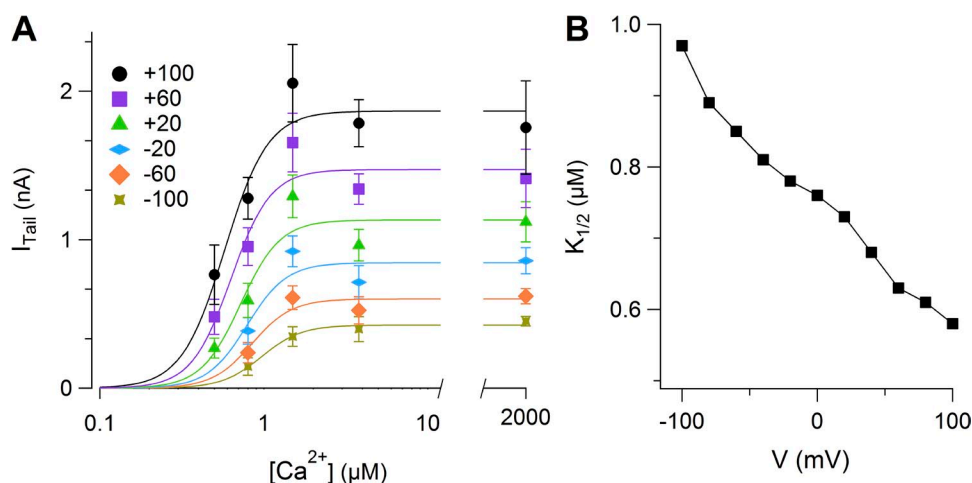

Figure 3. Ca^{2+} sensitivity. (A) Average instantaneous tail currents measured at -100 mV after a prepulse varying from -100 to 100 mV plotted versus $[\text{Ca}^{2+}]_i$ ($n = 4-8$). The continuous lines are the fit with the Hill equation (Eq. 1). (B) $K_{1/2}$ values plotted versus the prepulse voltage. Data in A are represented as mean \pm SEM.

To analyze the Ca^{2+} dependence of current activation, we measured dose-response relations by calculating instantaneous tail currents at -100 mV after prepulses ranging from -100 to 100 mV with a duration between 200 and 800 ms (Fig. 3 A). The average instantaneous tail currents were plotted versus $[\text{Ca}^{2+}]_i$ and fit at each voltage by the Hill equation:

$$I = I_{\text{max}} \frac{[\text{Ca}^{2+}]_i^{n_H}}{([\text{Ca}^{2+}]_i^{n_H} + K_{1/2}^{n_H})}, \quad (1)$$

where I is the current, I_{max} is the maximal current, $K_{1/2}$ is the $[\text{Ca}^{2+}]_i$ producing 50% of I_{max} , and n_H is the Hill coefficient.

Fig. 3 B shows that $K_{1/2}$ decreased with membrane depolarization from $0.97 \mu\text{M}$ at -100 mV to $0.58 \mu\text{M}$ at 100 mV. The Hill coefficient was not voltage dependent with a value ranging between 3 and 4. These results show that Ca^{2+} sensitivity is slightly voltage dependent and that binding of more than 3 Ca^{2+} ions is necessary to open the channel. It should be noted, however, that the current amplitudes at high Ca^{2+} concentrations were sometimes smaller than those at $1.5 \mu\text{M}$ Ca^{2+} (Fig. 3 A), and that this current decrease may have slightly affected the estimation

of n_H and $K_{1/2}$. A decline of currents at high Ca^{2+} concentrations has been described previously in some native Ca^{2+} -activated Cl^- currents (Kuruma and Hartzell, 2000; Qu et al., 2003), as well as in some splice variants of TMEM16A (Ferrera et al., 2009; Yang et al., 2014).

To estimate the voltage dependence of channel activation (G-V relation), we increased the amplitude of voltage steps to 160 mV and calculated instantaneous tail currents at -100 mV. G-V relations were fit by the Boltzmann equation:

$$G = G_{\text{max}} / \{1 + \exp[z(V_{1/2} - V)F/RT]\}, \quad (2)$$

where G is the conductance, G_{max} is the maximal conductance, z is the equivalent gating charge associated with voltage-dependent channel opening, V is the membrane potential, $V_{1/2}$ is the membrane potential producing 50% of G_{max} , F is the Faraday constant, R is the gas constant, and T is the absolute temperature.

Fig. 4 A shows the average G-V relations at the indicated $[\text{Ca}^{2+}]_i$. Continuous lines were obtained from a global fit of the average G-V relations with the same G_{max} . The average $V_{1/2}$ was 197 ± 39 mV ($n = 4$) at $0.5 \mu\text{M}$

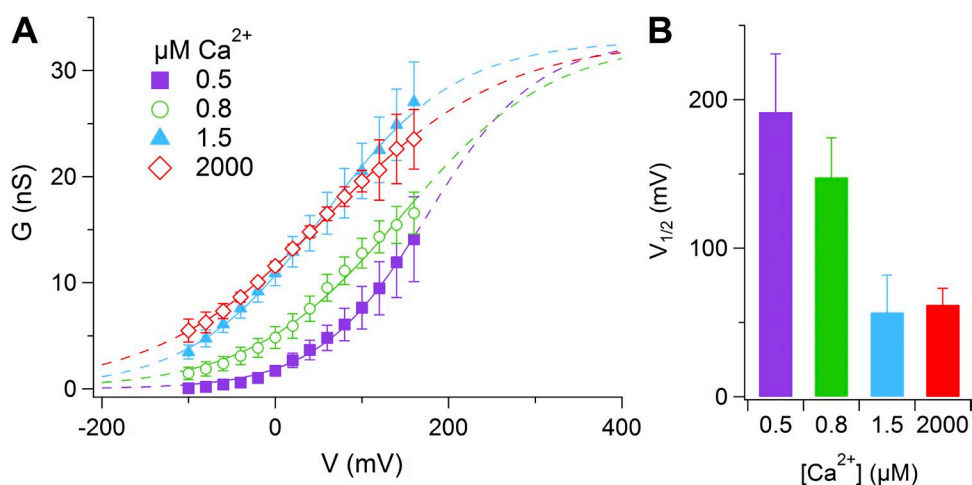

Figure 4. Voltage dependence of Ca^{2+} -activated currents. (A) Average conductances at the indicated $[\text{Ca}^{2+}]_i$ measured from instantaneous tail currents at -100 mV after prepulses from -100 to 160 mV plotted versus the prepulse voltage ($n = 4-8$). The continuous lines are the fit with the Boltzmann equation (Eq. 2). (B) Average $V_{1/2}$ values plotted versus $[\text{Ca}^{2+}]_i$ ($n = 4-8$). Data are represented as mean \pm SEM.

Ca^{2+} and became 70 ± 25 mV ($n = 6$) at $1.5 \mu\text{M}$ Ca^{2+} (Fig. 4 B), whereas the equivalent gating charge was not largely modified ($z = 0.39$ and 0.34 , respectively).

These results show that an increase in $[\text{Ca}^{2+}]_i$ caused a leftward shift of the G-V relation. Thus, the conductance

depends both on $[\text{Ca}^{2+}]_i$ and voltage, and depolarization can activate more channels as $[\text{Ca}^{2+}]_i$ is increased.

To investigate if the Ca^{2+} -activated currents are caused by cation channels, we first substituted Na^+ in the Ringer's solution with choline, as this large organic cation is

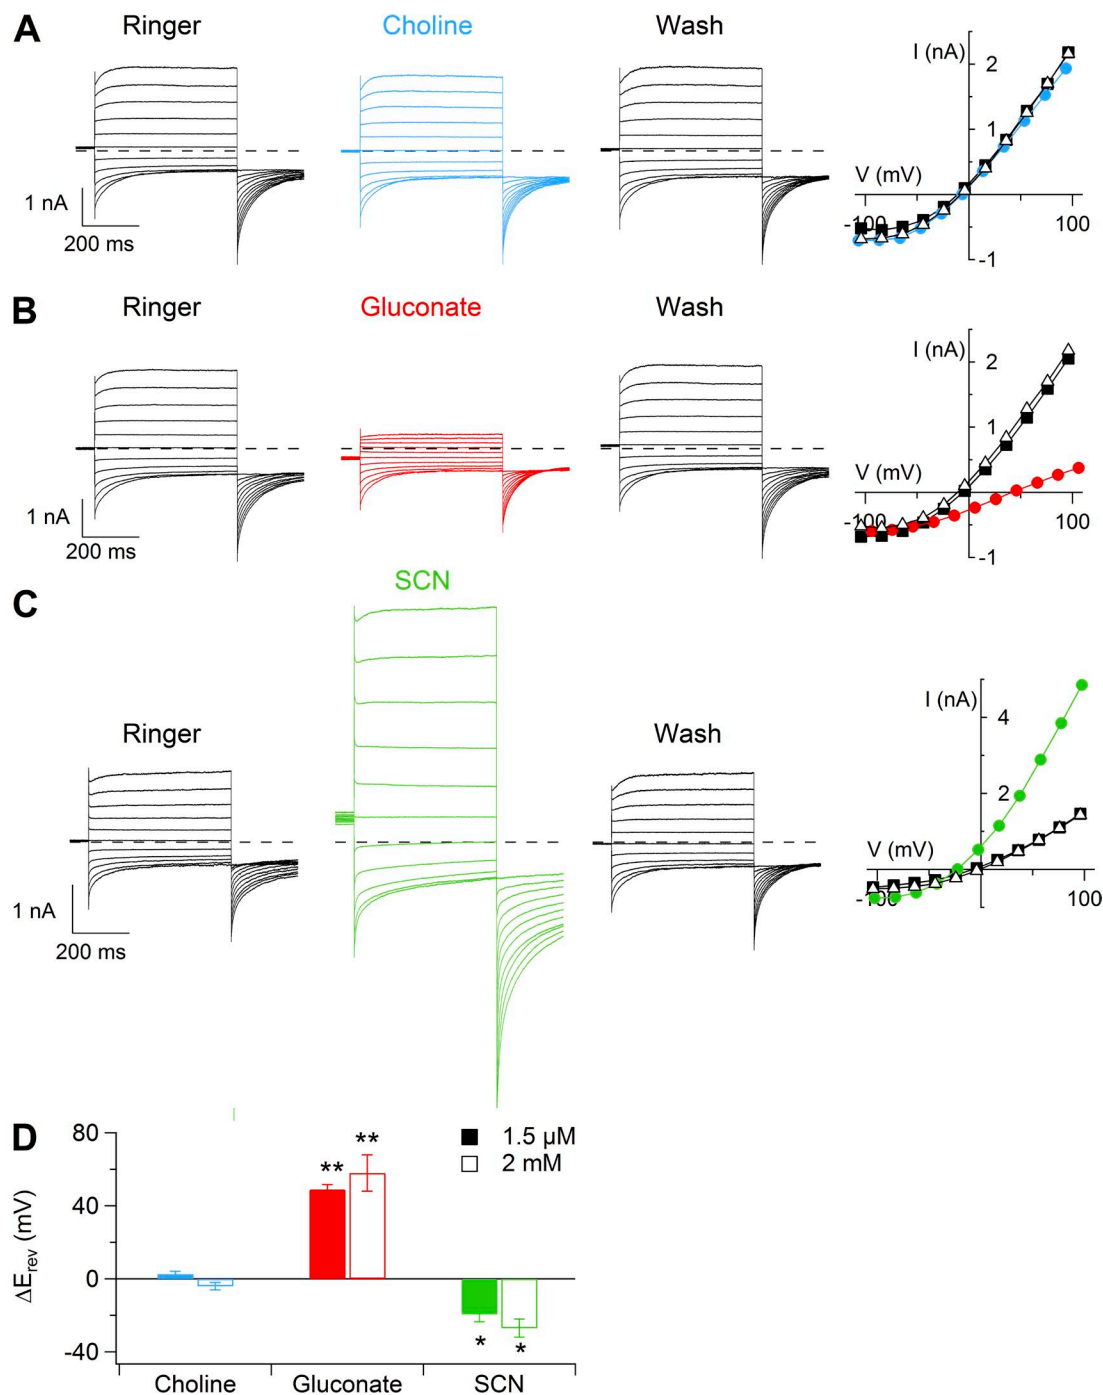

Figure 5. Ionic selectivity of Ca^{2+} -activated currents. Representative whole-cell recordings obtained with an intracellular solution containing $1.5 \mu\text{M}$ Ca^{2+} . Voltage protocol as in Fig. 1 A. Each neuron was exposed to a Ringer's solution containing NaCl , choline-Cl (A), Na-gluconate (B), or NaSCN (C), followed by washout in Ringer's solution with NaCl . Dashed lines indicate zero current. Steady-state I-V relationships measured at the end of the voltage steps are shown at the right of each set of recordings. (D) Average reversal potential shift upon substitution of extracellular NaCl with choline-Cl, Na-gluconate, or NaSCN in $1.5 \mu\text{M}$ (closed bars; $n = 5-10$) or 2 mM Ca^{2+} (open bars; $n = 4$). Data in D are represented as mean \pm SEM (**, $P < 0.01$; *, $P < 0.05$; Wilcoxon Signed Rank test).

usually impermeant in cation channels (Hille, 2001). Fig. 5 A shows representative recordings at $1.5 \mu\text{M}$ Ca^{2+} in the presence of NaCl, after replacement of Na^+ with choline, and in NaCl after washout. Steady-state I-V relations plotted in Fig. 5 B show that the replacement of Na^+ with choline did not modify the I-V relation. Similar results were obtained with 2 mM Ca^{2+} . The average reversal potential in choline-Cl was $-10 \pm 4 \text{ mV}$ ($n = 5$), not significantly different from the value of $-7 \pm 2 \text{ mV}$ ($n = 5$) measured in NaCl. The average shift of reversal potential in choline-Cl with respect to NaCl was not significantly different in $1.5 \mu\text{M}$ or 2 mM Ca^{2+} (Fig. 5 D), indicating that the Ca^{2+} -activated current at both Ca^{2+} concentrations was not a cation current.

Anion selectivity was then tested by replacing 140 mM NaCl with equimolar amounts of Na-gluconate or NaSCN (Fig. 5, C and E). When Cl^- was replaced with gluconate in the presence of $1.5 \mu\text{M}$ Ca^{2+} , we measured an average shift of V_{rev} of $49 \pm 3 \text{ mV}$ ($n = 10$), whereas in the presence of SCN^- the V_{rev} shift was $-20 \pm 3 \text{ mV}$ ($n = 8$). Similar values were obtained in the presence of 2 mM Ca^{2+} (Fig. 5 D). The average permeability ratios for anions (P_X/P_{Cl}) were: SCN^- (2.6) $>$ Cl^- (1.0) $>$ gluconate (0.1).

We investigated whether the more permeant anion SCN^- modifies the voltage dependence of channel activation and the gating kinetics, as observed in several

native Ca^{2+} -activated Cl^- currents (Greenwood and Large, 1999; Perez-Cornejo et al., 2004), as well as in heterologously expressed TMEM16A and TMEM16B (Xiao et al., 2011; Betto et al., 2014). Fig. 6 (A and B) shows recordings and I-V relations from a vomeronasal neuron in the presence of $0.5 \mu\text{M}$ Ca^{2+} when NaCl was replaced with NaSCN. The G-V relation was shifted toward more negative potentials when Cl^- was substituted with SCN^- (Fig. 6 C). The average $V_{1/2}$ from several neurons significantly changed from $168 \pm 6 \text{ mV}$ in Cl^- to $39 \pm 14 \text{ mV}$ in SCN^- ($n = 3$). Moreover, τ_{act} in the presence of $0.5 \mu\text{M}$ Ca^{2+} became significantly faster in SCN^- , with an average value at 100 mV of $94 \pm 12 \text{ ms}$ ($n = 3$), compared with $282 \pm 49 \text{ ms}$ ($n = 3$) in Cl^- (Fig. 6 E). Also, the deactivation time constants, measured as in Fig. 2 D, were significantly modified upon anion substitution (Fig. 6 F), with average values of $\tau_{\text{deact}1} = 4.2 \pm 0.9 \text{ ms}$ and $\tau_{\text{deact}2} = 57 \pm 2 \text{ ms}$ ($n = 3$) in SCN^- , slower than the values in Cl^- measured in the same neurons: $\tau_{\text{deact}1} = 10 \pm 2 \text{ ms}$ and $\tau_{\text{deact}2} = 183 \pm 16 \text{ ms}$ ($n = 3$).

To assess the pharmacological profile of Ca^{2+} -activated Cl^- currents in vomeronasal sensory neurons, we measured the extracellular blockage properties of $300 \mu\text{M}$ NFA, $10 \mu\text{M}$ $\text{CaCC}_{\text{inh}}\text{-A01}$, and 1 mM A9C, commonly used blockers of Ca^{2+} -activated Cl^- currents (De La Fuente et al., 2008; Hartzell et al., 2009; Huang et al.,

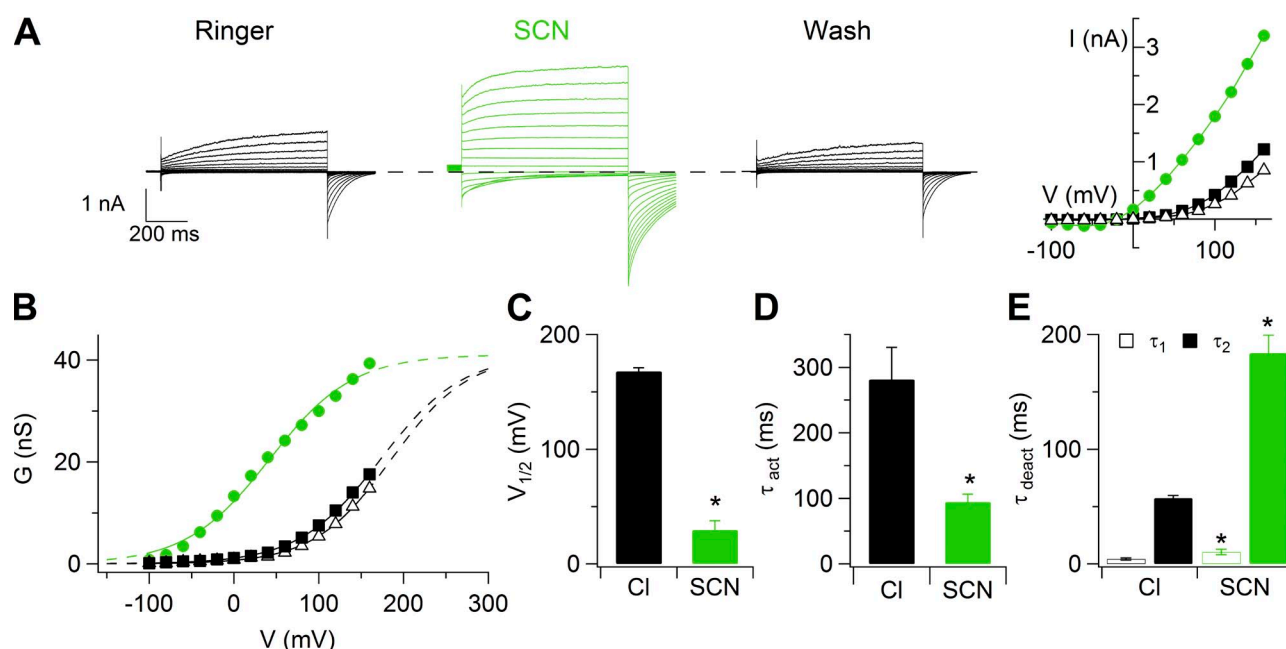

Figure 6. Change of voltage dependence in the presence of SCN^- . (A) Representative whole-cell recordings obtained with an intracellular solution containing $0.5 \mu\text{M}$ Ca^{2+} . The same neuron was exposed to a Ringer's solution containing NaCl or NaSCN, followed by washout in Ringer's solution with NaCl. Voltage steps of 800-ms duration were given from a holding voltage of 0 mV to voltages between -100 and 160 mV in 20-mV steps, followed by a step to -100 mV . Dashed lines indicate zero current. Steady-state I-V relationships measured at the end of the voltage steps. (B) Conductances measured from instantaneous tail currents at -100 mV after prepulses from -100 to 160 mV plotted versus the prepulse voltage. Data from the recordings shown in A. (C) Average $V_{1/2}$ in Cl^- or SCN^- ($n = 3$). (D and E) Average activation and deactivation time constants in Cl^- or SCN^- ($n = 3$). Data in C–E are represented as mean \pm SEM (*, $P < 0.05$; Wilcoxon Signed Rank test).

2012). Fig. 7 shows that all three compounds induced a reversible block of the outward currents activated by $1.5 \mu\text{M}$ Ca^{2+} , whereas inward currents were blocked only by NFA and $\text{CaCC}_{\text{inh}}\text{-A01}$. The percentage of current in the presence of each compound relative to control was measured both at 2 ms after the voltage step (early current) and at the end of the voltage step (late current), as shown in Fig. 7 (G and H). At 100 mV, the percentage of late currents was 29 ± 5 for NFA, 38 ± 5 for $\text{CaCC}_{\text{inh}}\text{-A01}$, and 29 ± 7 for A9C (Fig. 7 G; $n = 5-7$), and similar values were obtained by measuring the early currents

(Fig. 7 H). At -100 mV, both NFA and $\text{CaCC}_{\text{inh}}\text{-A01}$ partially blocked the inward late currents with the following percentages: 48 ± 13 for NFA and 46 ± 7 for $\text{CaCC}_{\text{inh}}\text{-A01}$ (Fig. 7 G). These values were not significantly different when measured as early currents (Fig. 7 H). On the contrary, A9C did not significantly affect the inward early current at -100 mV but greatly potentiated the inward late current with a percentage of 200 ± 55 (Fig. 7, G and H).

These results show that, in the presence of $1.5 \mu\text{M}$ Ca^{2+} , $300 \mu\text{M}$ NFA and $10 \mu\text{M}$ $\text{CaCC}_{\text{inh}}\text{-A01}$ produced

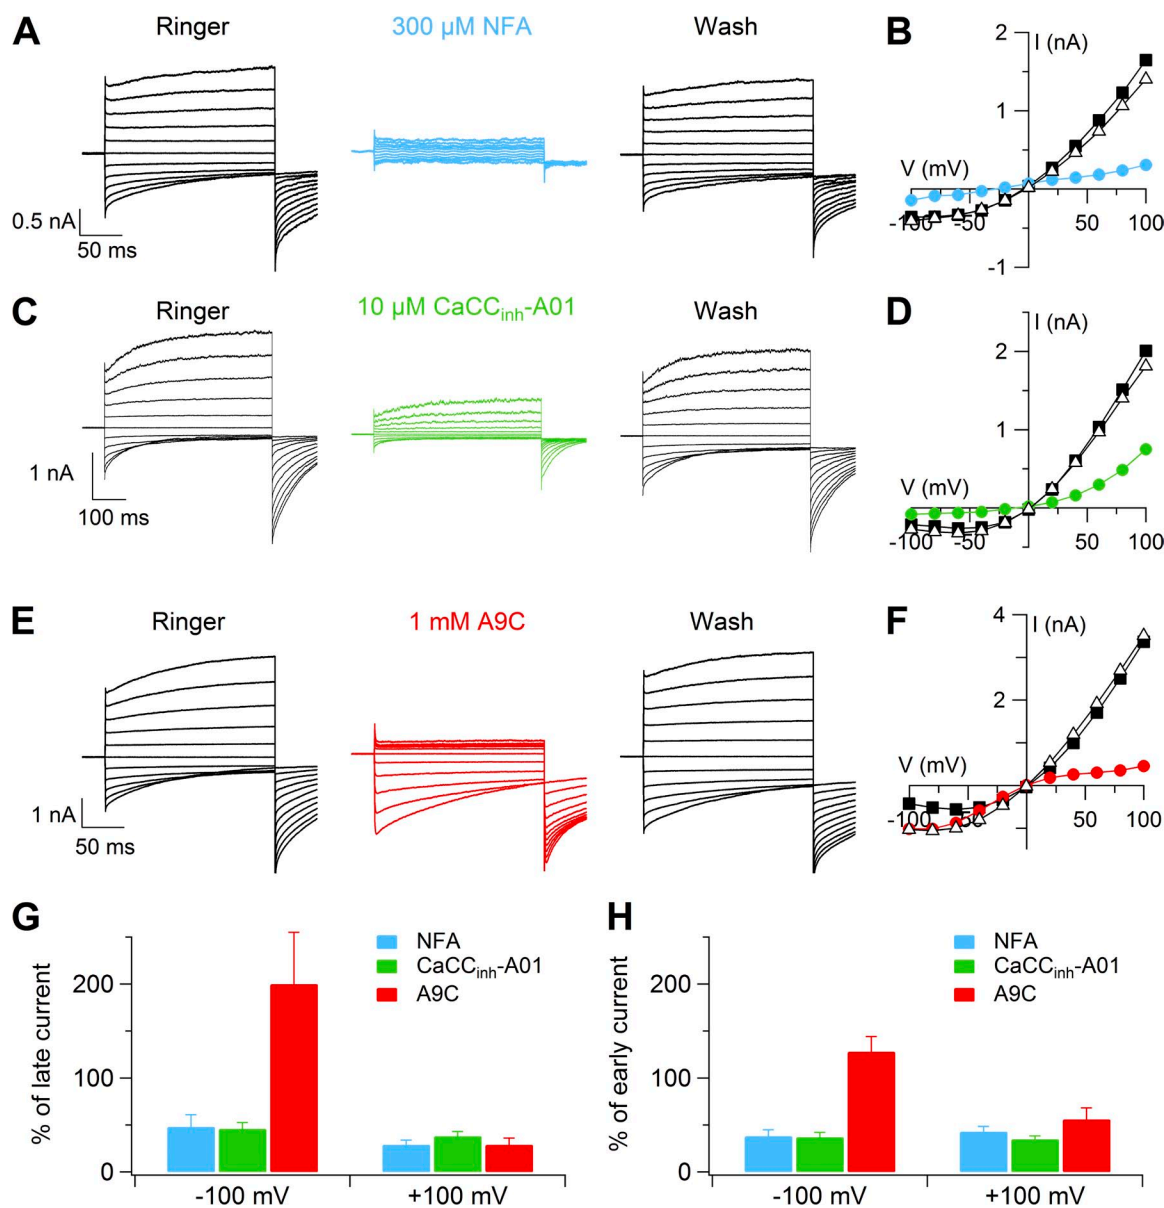

Figure 7. Pharmacology of Ca^{2+} -activated currents. Representative whole-cell recordings obtained with an intracellular solution containing $1.5 \mu\text{M}$ Ca^{2+} . Voltage protocol as in Fig. 1 A. Each neuron was exposed to a Ringer's solution to $300 \mu\text{M}$ NFA (A), $10 \mu\text{M}$ $\text{CaCC}_{\text{inh}}\text{-A01}$ (C), or 1 mM A9C (E), and again to Ringer's solution. (B, D, and F) I-V relationships measured at the end of the voltage steps from the recordings shown on the left. (G and H) Average percentages of currents measured in the presence of each compound relative to control at the end of the voltage step (G; late current) or 2 ms after the voltage step (H; early current) at -100 or 100 mV ($n = 5-7$). Data in G and H are represented as mean \pm SEM.

similar current inhibitions at 100 and -100 mV both for early and late currents. 1 mM A9C had an anomalous effect, blocking the current at 100 mV and largely potentiating late currents at -100 mV.

Collectively, these results show that the Ca^{2+} -activated currents measured in vomeronasal sensory neurons are mainly anion currents.

TMEM16A and TMEM16B are coexpressed in microvilli of vomeronasal sensory neurons (Dibattista et al., 2012), and their individual heterologous expression shows some similar electrophysiological properties—indeed, they cannot be distinguished by their ionic selectivity (Adomaviciene et al., 2013) or by their pharmacological profile (Pifferi et al., 2009a; Bradley et al., 2014)—as well as some important differences: TMEM16A have a higher Ca^{2+} sensitivity and slower activation kinetics than TMEM16B (Caputo et al., 2008; Schroeder et al., 2008; Yang et al., 2008; Pifferi et al., 2009a; Stephan et al., 2009; Ferrera et al., 2011; Cenedese et al., 2012; Pedemonte and Galletta, 2014). We found that whole-cell properties of Ca^{2+} -activated Cl^- currents in vomeronasal neurons are more similar to those of heterologous TMEM16A than TMEM16B.

Ca^{2+} -activated Cl^- currents in inside-out excised patches from dendritic knob/microvilli of mouse vomeronasal sensory neurons

To further characterize Ca^{2+} -activated currents, we excised membrane patches in the inside-out configuration from dendritic knobs of vomeronasal neurons. Membrane patches were excised from the tips of the knobs and are likely to contain membranes from both the dendritic knob and from microvilli. Fig. 8 A shows the change of current at -50 mV when an inside-out patch was exposed to $100 \mu\text{M}$ Ca^{2+} for 2 s. Upon the application of $100 \mu\text{M}$ Ca^{2+} , the current rapidly reached a value of about -40 pA and remained stationary in the presence of Ca^{2+} , whereas it rapidly returned to the baseline value when Ca^{2+} was removed. The average current from several patches at -50 mV was -16 ± 5 pA (range of -6 to -40 pA; $n = 7$), and the average ratio between the current measured 2 s after Ca^{2+} application and the current measured shortly after Ca^{2+} application was 0.96 ± 0.02 ($n = 7$).

Fig. 8 B shows that the amplitude of Ca^{2+} -activated currents in inside-out patches decreased with time after patch excision. A similar current rundown has also been

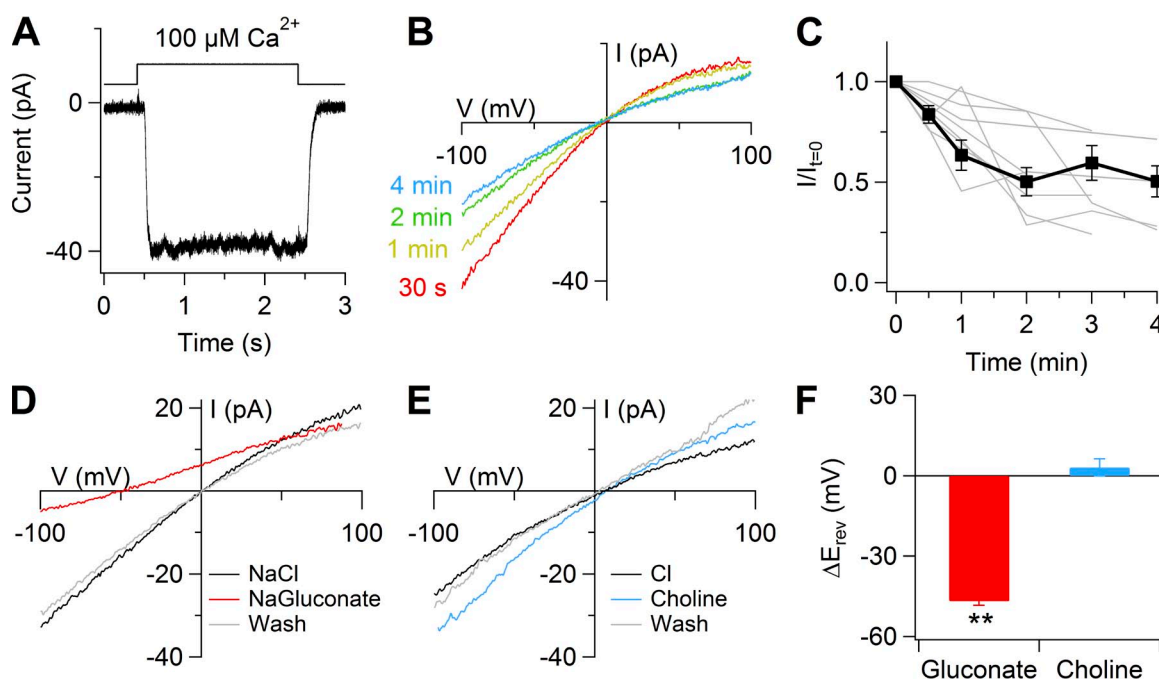

Figure 8. Rundown and ionic selectivity of Ca^{2+} -activated currents in inside-out patches from dendritic knob/microvilli of vomeronasal sensory neurons. (A) An inside-out patch was exposed to $100 \mu\text{M}$ Ca^{2+} for 2 s at the time indicated in the upper trace. Holding potential, -50 mV. Symmetrical NaCl solutions. (B) I-V relations from a voltage ramp protocol. Leakage currents measured in 0 Ca^{2+} were subtracted. The number next to each trace indicates the time of Ca^{2+} application after patch excision. (C) Average ratios between currents at -100 mV measured at the indicated times after patch excision and the current measured at patch excision ($n = 3-10$). Ratios of individual patches are in gray. (D and E) I-V relations activated by $100 \mu\text{M}$ Ca^{2+} from a voltage ramp protocol after subtraction of the leakage currents measured in 0 Ca^{2+} . The patch was exposed to bath solutions containing 140 mM NaCl, Na-gluconate (D), or choline-Cl (E), followed by washout with NaCl. Current traces in D and E were from the same patch. (F) Average reversal potential shift upon substitution of extracellular NaCl with Na-gluconate or choline-Cl ($n = 3$) (**, $P < 0.01$; Wilcoxon Signed Rank test). Error bars indicate SEM.

observed in other native Ca^{2+} -activated Cl^- currents, as well as in heterologous TMEM16A and TMEM16B currents (Kuruma and Hartzell, 2000; Qu and Hartzell, 2000; Reisert et al., 2003; Pifferi et al., 2009a,b; Stephan et al., 2009; Yu et al., 2014). Currents underwent an irreversible reduction until they reached an almost steady-state value (Fig. 8, B and C).

To determine the ion selectivity of the Ca^{2+} -activated current, we replaced NaCl in the bathing solution with Na-glucuronate or with choline-Cl and measured the shift of reversal potential (Fig. 8, D–F). Currents were activated by $100 \mu\text{M}$ Ca^{2+} , and voltage ramps from -100 to 100 mV were applied. When Cl^- was replaced with glucuronate, we measured an average shift of V_{rev} of -47 ± 2 mV ($n = 3$), whereas in the presence of choline-Cl, the shift of V_{rev} was 3 ± 3 mV ($n = 3$). Thus, replacement of Cl^- with glucuronate shifted the reversal potential from near zero in symmetrical Cl^- to more negative values, as expected for Cl^- -selective channels in our experimental conditions, showing that Ca^{2+} -activated currents were Cl^- selective.

To measure dose–response relations, we activated currents in excised inside-out patches with various Ca^{2+} concentration and measured current amplitudes after the rapid phase of rundown, when the current reached an almost steady-state value (Fig. 9, A–D). Fig. 9 C shows that $K_{1/2}$ decreased with membrane depolarization from $1.5 \pm 0.2 \mu\text{M}$ at -100 mV to $1.1 \pm 0.1 \mu\text{M}$ ($n = 5$) at 100 mV. The Hill coefficient was not voltage dependent with a value ranging between 2.4 and 3.2. The average ratio between currents at 100 and -100 mV was 1.3 ± 0.3 at $1 \mu\text{M}$ ($n = 5$) and 0.65 ± 0.05 at $100 \mu\text{M}$ ($n = 13$).

Collectively, these results demonstrate the presence of Ca^{2+} -activated Cl^- currents in the knob/microvilli of mouse vomeronasal sensory neurons. Moreover, the range of Ca^{2+} sensitivity and the absence of inactivation in the presence of a constant Ca^{2+} concentration indicate that properties of native currents are more similar to those of TMEM16A than TMEM16B (see also Discussion). Indeed, all isoforms of TMEM16B have been shown to inactivate in the continuous presence of Ca^{2+} at negative potentials (Pifferi et al., 2009a; Stephan et al., 2009; Ponissery Saidu et al., 2013), whereas TMEM16A current did not inactivate (Ni et al., 2014; Tien et al., 2014; Yu et al., 2014).

Conditional knockout of TMEM16A in vomeronasal sensory neurons

We have shown previously that TMEM16A and TMEM16B are coexpressed in microvilli of mouse vomeronasal sensory neurons (Dibattista et al., 2012), and we showed here that Ca^{2+} -activated Cl^- currents in vomeronasal sensory neurons are more similar to heterologous TMEM16A than TMEM16B. As the constitutive TMEM16A knockout is lethal soon after birth (Rock et al., 2008), we selectively abolished expression of TMEM16A in mature vomeronasal sensory neurons by crossing floxed TMEM16A^{fl/fl} mice (Faria et al., 2014; Schreiber et al., 2014) with OMP-Cre mice (Li et al., 2004).

By immunohistochemistry, we confirmed our previous results that TMEM16A and TMEM16B are expressed at the apical surface of the vomeronasal epithelium of control WT mice (Fig. 10, A and B), whereas we showed

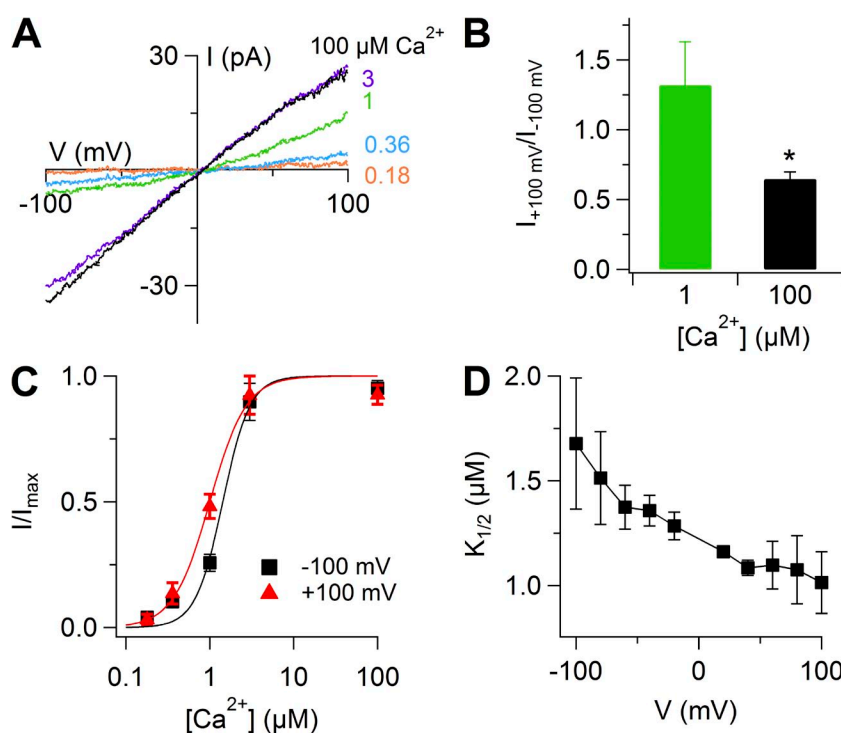

Figure 9. Dose–response relations of Ca^{2+} -activated currents in inside-out patches from the dendritic knob/microvilli of vomeronasal sensory neurons. (A) I–V relations from the same patch exposed to the indicated Ca^{2+} concentrations after subtraction of the currents measured in 0 Ca^{2+} . (B) Ratios between currents measured at 100 and at -100 mV at the indicated Ca^{2+} concentrations ($n = 5$ – 13). *, $P < 0.05$; Wilcoxon Signed Rank test. (C) Dose–response relations, obtained by normalized currents at -100 or 100 mV ($n = 5$). Continuous lines are the fit with the Hill equation (Eq. 1). (D) Mean $K_{1/2}$ values plotted versus voltage ($n = 5$). Error bars indicate SEM.

that TMEM16A immunoreactivity was absent in TMEM16A cKO mice (Fig. 10 C). Furthermore, we investigated by immunohistochemistry if the lack of TMEM16A affected the expression of TMEM16B and TRPC2, and found a normal pattern of expression for the two proteins (Fig. 10, D and F). In addition, we verified the specificity of *Tmem16A* ablation, by checking TMEM16A expression in lateral nasal glands and septal nasal glands, which do not express OMP and should therefore express TMEM16A. Indeed, Fig. 10 (G and H) shows expression of TMEM16A in the nasal glands of TMEM16A cKO mice.

These results demonstrate that the loss of TMEM16A is restricted to vomeronasal sensory neurons of cKO mice and confirm the specificity of the antibody against this protein. Furthermore, TMEM16B and TRPC2 are expressed at the apical surface of the vomeronasal epithelium in cKO as in WT mice.

To determine the contribution of TMEM16A to Ca^{2+} -activated Cl^- currents in vomeronasal sensory neurons, we measured currents in isolated neurons from TMEM16A cKO mice in the whole-cell configuration with intracellular solutions containing various amounts of free $[\text{Ca}^{2+}]_i$. Fig. 11 (A and B) shows the comparison

between representative recordings from TMEM16A^{fl/fl} and TMEM16A cKO mice. Currents were activated by voltage steps between -100 and 100 mV from a holding potential of 0 mV, followed by a step to -100 mV and return to 0 mV. The last part of the current trace elicited by the depolarizing voltage from -100 to 0 mV was used as a control of the viability of neurons, as it allowed the measurement of voltage-gated inward currents (likely Na^+ currents; insets of Fig. 11, A and B). The kinetics of currents activated by $1.5 \mu\text{M}$ Ca^{2+} in neurons from TMEM16A^{fl/fl} mice resembled those measured in control WT mice (Figs. 11 A and 1 A), whereas currents in vomeronasal neurons from TMEM16A cKO mice were not significantly different from currents in the absence of Ca^{2+} (Figs. 11, B and C, and 1 A). The inset of Fig. 11 B shows a representative voltage-gated current (elicited by a 0 -mV step from -100 mV), indicating that the neuron was viable but did not have currents activated by Ca^{2+} . All together, we tested 40 viable neurons from 6 TMEM16A cKO mice at $[\text{Ca}^{2+}]_i$ varying from $0.5 \mu\text{M}$ to 2 mM Ca^{2+} and did not find a significant difference from currents measured in 0 Ca^{2+} . Furthermore, we measured currents in inside-out patches from dendritic knobs of vomeronasal neurons from TMEM16A

Figure 10. Immunostaining of sections of VNO in WT and TMEM16A cKO mice. (A and B) Confocal micrographs showing TMEM16A (red) and TMEM16B (green) expression at the apical surface of the vomeronasal epithelium in WT mice. (C–F) No immunoreactivity to TMEM16A was detectable at the apical surface of the vomeronasal epithelium in TMEM16A cKO mice, whereas TMEM16B and TRPC2 were normally detected. (G–H) As a control, expression of TMEM16A is shown in nasal septal glands (G) and lateral nasal glands (H) of cKO mice. Cell nuclei were stained by DAPI (blue). Bars, $10 \mu\text{m}$.

cKO mice and did not find any measurable Ca^{2+} -activated current (not depicted).

These results demonstrate that TMEM16A is a necessary component of the Ca^{2+} -activated Cl^- current in vomeronasal sensory neurons.

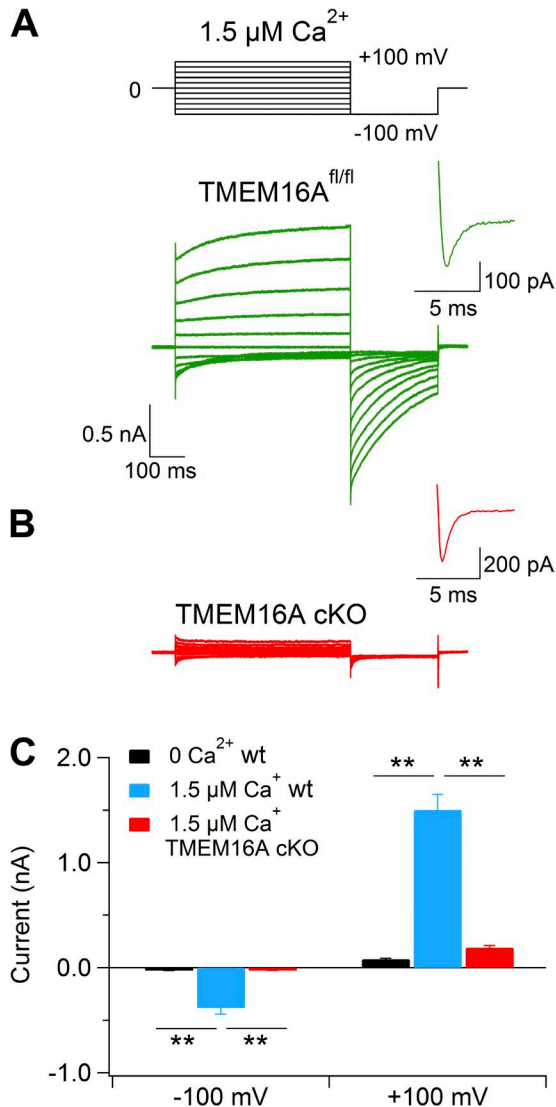

Figure 11. Lack of Ca^{2+} -activated currents in vomeronasal sensory neurons from TMEM16A conditional knockout mice. Representative whole-cell recordings obtained with an intracellular solution containing 1.5 μM Ca^{2+} from vomeronasal sensory neurons dissociated from TMEM16A^{fl/fl} (A) or TMEM16A cKO (B) mice. Insets show the enlargement of the recordings of voltage-gated inward currents activated by a step to 0 mV from the holding potential of -100 mV, as indicated in the voltage protocol at the top of the figure. (C) Mean current amplitudes measured at -100 or 100 mV with intracellular pipette solution containing nominally 0 (black bar; $n = 6$) or 1.5 μM free Ca^{2+} from WT (blue bar; $n = 28$) or TMEM16A cKO mice (red bar; $n = 20$). Error bars indicate SEM (**, $P < 0.01$; Dunn–Hollander–Wolfe test after Kruskal–Wallis analysis).

DISCUSSION

In this study, we have provided the first functional characterization of Ca^{2+} -activated Cl^- currents in isolated mouse vomeronasal sensory neurons both in whole-cell and in inside-out patches from the knobs/microvilli. A comparison among biophysical properties indicates that native currents are more similar to heterologous TMEM16A than to TMEM16B Ca^{2+} -activated Cl^- currents. Furthermore, conditional knockout of TMEM16A abolished Ca^{2+} -activated currents in mouse vomeronasal neurons, demonstrating that TMEM16A is a necessary component of Ca^{2+} -activated Cl^- currents in these neurons.

Ca^{2+} -activated currents

In whole-cell recordings, we measured Ca^{2+} -activated currents in 70% of the neurons (124/178), whereas we did not record any Ca^{2+} -activated current in the remaining neurons (30%; 54/178), although these neurons were considered viable, as they had transient voltage-gated inward currents (likely Na^+ currents). These currents were recorded with intracellular Cs^+ or Na^+ instead of K^+ , i.e., under ionic conditions that prevented permeation through Ca^{2+} -activated K^+ channels. The absence of Ca^{2+} -activated currents in some neurons could simply be caused by inactivation or rundown of Ca^{2+} -activated channels, or to damage of the microvilli, where these channels should be mostly expressed (as it will be discussed later), but it also raises the question of whether a Ca^{2+} -activated current is present only in a subset of vomeronasal neurons. Indeed, the mouse vomeronasal epithelium contains two major populations of neurons, basal and apical, based on their location and on the expression of different receptors and proteins (Berghard and Buck, 1996; Jia and Halpern, 1996; Lau and Cherry, 2000; Martini et al., 2001; Leinders-Zufall et al., 2004; Liberles et al., 2009; Rivière et al., 2009). Apical neurons express receptors of the V1R or FPR families, the G protein α subunit $\text{G}\alpha\text{i}2$, and phosphodiesterase 4A, whereas basal neurons express receptors of the V2R or FPR families and the G protein α subunit $\text{G}\alpha\text{o}$. We have previously investigated by immunocytochemistry the percentage of apical and basal neurons obtained in our dissociated preparations using anti-phosphodiesterase 4A antibody as a marker for apical neurons, or anti- $\text{G}\alpha\text{o}$ antibody as a marker for basal neurons, and found that on average, $\sim 74\%$ of the dissociated neurons were apical (Celsi et al., 2012). Based on these results, it is very likely that most of our electrophysiological recordings were obtained from apical neurons, and it is possible to speculate that the 30% of neurons without Ca^{2+} -activated current could be basal neurons. However, in the dissociated preparations used for electrophysiological recordings, we could not determine by visual inspection whether a neuron was apical or basal, nor we could perform immunocytochemistry after the recordings, as neurons were

often lost after pipette retrieval. It is important to note that TMEM16A and TMEM16B are coexpressed both in apical and basal neurons (Dibattista et al., 2012). Thus, we favor the interpretation that all neurons have Ca^{2+} -activated currents and that the absence of these currents in some neurons was likely caused by channel inactivation or rundown or to damage of the microvilli, although we cannot exclude the possibility that Ca^{2+} -activated currents are present only in a subset of vomeronasal neurons.

Cationic and anionic Ca^{2+} -activated currents

Previous studies on vomeronasal sensory neurons have reported the presence of Ca^{2+} -activated currents, in the absence of intracellular K^+ , with different ionic selectivity: nonselective cation currents or anion currents.

Ca^{2+} -activated nonselective cation currents have been recorded in the hamster (Liman, 2003) and in the mouse (Spehr et al., 2009), although they showed different Ca^{2+} sensitivities. In the hamster, whole-cell dialysis with 0.5–2 mM Ca^{2+} produced currents with an average amplitude of -177 pA at -80 mV, and half-activation of this current required a high Ca^{2+} concentration of 0.5 mM at -80 mV (Liman, 2003). In the mouse, nonselective cation currents were recorded in inside-out patches only in a subpopulation of neurons (12.5%) in the presence of 50 μM Ca^{2+} (Spehr et al., 2009). In a previous study by our group (Dibattista et al., 2012), we used photolysis of caged Ca^{2+} to increase Ca^{2+} concentration in the apical region (dendritic knob and microvilli) of mouse vomeronasal neurons, and we did not detect any cation current, but we measured Ca^{2+} -activated Cl^- currents with an average amplitude of -261 pA at -50 mV. In that study, we pointed out that the highest Ca^{2+} concentration obtained from photolysis of caged Ca^{2+} was probably ~ 10 – 20 μM , lower than the values used to activate the nonselective cation currents in the previous studies (Liman, 2003; Spehr et al., 2009), and that perhaps a higher Ca^{2+} concentration could activate nonselective cation currents. However, in the present study, we dialyzed neurons also using high Ca^{2+} concentrations in the pipette, reaching 2 mM, and did not record any cation current. Indeed, the substitution of extracellular NaCl with choline-Cl did not cause a significant shift in the reversal potential both with 1.5 μM and 2 mM of intracellular Ca^{2+} , whereas the substitution of NaCl with Na-gluconate caused a shift in the reversal potential, as expected for Cl^- currents. The substitution of extracellular Cl^- with SCN^- showed that this anion is more permeant than Cl^- and also altered the voltage dependence of the Ca^{2+} -activated current, a common characteristic of Ca^{2+} -activated Cl^- channels (Perez-Cornejo et al., 2004; Xiao et al., 2011; Betto et al., 2014). Moreover, the typical Cl^- blockers NFA and $\text{CaCC}_{\text{inh}}\text{A01}$ caused a reversible inhibition of the current. A9C had an anomalous effect, causing a current decrease at positive voltages and a current increase at negative voltages, consistent

with previous results observed in Ca^{2+} -activated Cl^- channels in smooth muscle cells (Piper and Greenwood, 2003; Cherian et al., 2015).

Furthermore, we performed inside-out recordings from the knobs/microvilli of mouse vomeronasal neurons and demonstrated the presence of Ca^{2+} -activated Cl^- channels with electrophysiological properties similar to those of TMEM16A. We therefore suggest that the nonselective cation current measured in vomeronasal neurons from the hamster may be species specific. In the mouse, results obtained in 12.5% of inside-out patches from Spehr et al. (2009) could indicate that the presence of Ca^{2+} -activated nonselective cation channels is restricted to a very small subpopulation of vomeronasal neurons that was not present in our experiments.

Other studies have also reported evidence for Ca^{2+} -activated Cl^- currents in mouse vomeronasal sensory neurons. Yang and Delay (2010) used perforated patch recording on dissociated neurons and reported that the urine-activated current was partially blocked by some Cl^- channel blockers (NFA and DIDS), and was reduced by removing extracellular Ca^{2+} or by blocking intracellular Cl^- accumulation mediated by the NKCC1 cotransporter. Similar results were also obtained by Kim et al. (2011) using VNO slice preparations. At present, the source of intracellular Ca^{2+} increase is still unclear, as Yang and Delay (2010) showed that Ca^{2+} influx is necessary to activate a Cl^- current, whereas Kim et al. (2011) suggested that Cl^- currents could also be activated by Ca^{2+} release from internal store mediated by IP_3 in a TRPC2-independent manner. The presence of Ca^{2+} -activated Cl^- component in urine response indicates that these channels could play a role in vomeronasal transduction. However, at present, the Cl^- equilibrium potential in vomeronasal neurons in physiological conditions is unknown, preventing the possibility to determine if Ca^{2+} -activated Cl^- currents contribute to depolarization or hyperpolarization.

TMEM16A is a necessary component of the Ca^{2+} -activated Cl^- currents in mouse vomeronasal sensory neurons

Both the results of our whole-cell and inside-out experiments from mouse vomeronasal neurons showed the presence of Ca^{2+} -activated Cl^- currents with electrophysiological properties more similar to those of heterologous TMEM16A than TMEM16B currents. It is important to note that splice variants have been identified both for TMEM16A (Caputo et al., 2008; Ferrera et al., 2009, 2011) and for TMEM16B (Stephan et al., 2009; Ponissery Saidu et al., 2013), and it has been shown that some functional channel properties such as Ca^{2+} sensitivity and time and voltage dependence differ among the various isoforms of each protein (Ferrera et al., 2010; Huang et al., 2012; Pedemonte and Galiotta, 2014).

In whole-cell recordings, we measured a kinetics of activation with a time constant of ~ 235 ms at 100 mV in

0.5 μM Ca^{2+} , rather similar to the value of ~ 300 ms measured in the same conditions for the TMEM16A (abc) isoform (Scudieri et al., 2013), but very different from the fast kinetics, with time constants of activation < 10 ms, measured in the retinal isoforms of TMEM16B (Cenedese et al., 2012; Adomaviciene et al., 2013; Scudieri et al., 2013; Betto et al., 2014). However, time constants of activation for the olfactory isoforms of TMEM16B have not been estimated yet, and visual inspection of a whole-cell recording of the recently identified olfactory isoform B (Fig. 4 A of Ponissery Saidu et al., 2013) indicates that the kinetics could be slower than in the retinal isoforms.

In inside-out recordings, a comparison of dose–response relations shows that the Ca^{2+} concentration necessary for 50% activation of the maximal current at 60 or 70 mV had a value of 1.1 μM in our experiments, more similar to the value of 1.3 μM for TMEM16A (Adomaviciene et al., 2013) than to the value of 1.8–4 μM for TMEM16B (Pifferi et al., 2009a, 2012; Adomaviciene et al., 2013). Moreover, at the holding potential of -50 mV and in the presence of 100 μM Ca^{2+} , we did not measure a time-dependent decrease in the presence of Ca^{2+} , typical of all TMEM16B isoforms (Pifferi et al., 2009a, 2012; Stephan et al., 2009; Ponissery Saidu et al., 2013), but we observed a stationary current similar to the behavior of TMEM16A currents in inside-out patches (Ni et al., 2014; Tien et al., 2014; Yu et al., 2014).

To investigate the contribution of TMEM16A to Ca^{2+} -activated Cl^- currents in vomeronasal neurons, we obtained TMEM16A cKO mice and surprisingly found that Ca^{2+} -activated currents were abolished, demonstrating that TMEM16A is an essential component of Ca^{2+} -activated Cl^- currents in mouse vomeronasal sensory neurons. Immunohistochemistry showed the presence of TMEM16B at the apical surface of the vomeronasal epithelium TMEM16A cKO mice, indicating that the expression of TMEM16B does not depend on TMEM16A. At present, we do not know which splice variants are expressed in vomeronasal neurons, but Ponissery Saidu et al. (2013) showed that neurons of the main olfactory epithelium also express isoforms lacking the exon 4 sequence (named isoforms A Δ 4 or B Δ 4), which do not form functional channels by themselves but modulate channel properties of main olfactory isoforms (named A and B) when they are coexpressed. It is therefore tempting to speculate that vomeronasal neurons may express TMEM16B isoforms that do not form functional channels but could modulate the activity of TMEM16A. Previous results showed that TMEM16A coimmunoprecipitated with TMEM16B in heterologous systems, suggesting that these two proteins may form heteromers (Tien et al., 2014). Thus, native vomeronasal Ca^{2+} -activated Cl^- channels may be heteromers composed of two or more TMEM16A and TMEM16B isoforms. Moreover, our results show that TMEM16A

is necessary to have functional channels in the VNO, whereas VNO TMEM16B isoforms may not form functional channels by themselves but could be modulatory subunits of heteromeric channels.

However, in a previous study, Billig et al. (2011) compared whole-cell recordings in vomeronasal sensory neurons from WT ($n = 7$) or knockout mice for TMEM16B (Ano2 $^{-/-}$; $n = 6$) in the presence of 1.5 μM Ca^{2+} or 0 Ca^{2+} in the pipette, and reported that: “Currents of most Ano2 $^{-/-}$ VSNs were indistinguishable from those we observed without Ca^{2+} (Fig. 5n), but a few cells showed currents up to twofold larger. Averaged current/voltage curves revealed that Ca^{2+} -activated Cl^- currents of VSNs depend predominantly on Ano2 (Fig. 5l). Although Ano1 is expressed in the VNO (Fig. 3a), its contribution to VSN currents seems minor.” Thus, Billig et al. (2011) suggested that TMEM16B plays a prominent role in Ca^{2+} -activated currents in vomeronasal neurons. However, as the specific VNO TMEM16A and TMEM16B isoforms are presently unknown, there is an alternative possible explanation for the results observed by Billig et al. (2011); vomeronasal neurons may express one or more TMEM16A isoforms that do not form functional channels by themselves but may form functional heteromeric channels when coexpressed with specific TMEM16B isoforms.

Collectively, our data and those from Billig et al. (2011) raise the possibility that only heteromeric channels composed by the VNO-specific isoforms TMEM16A and TMEM16B are functional in vomeronasal neurons. In addition, we cannot exclude the possibility that different populations of neurons may express different isoforms at various levels, and that the two studies investigated different populations of vomeronasal neurons. Future experiments will have to identify the specific VNO isoforms and unravel their interactions.

We thank Peter Mombaerts (Max Planck Institute of Biophysics, Frankfurt, Germany) for providing OMP-Cre mice. We also thank Claudia Gargini (University of Pisa, Italy) for useful discussions, Gianluca Pietra for help with the production of cKO mice, and all members of the laboratory for discussions.

This study was supported by grants from the Italian Ministry of Education, University and Research (2010599KBR to A. Menini) and from the Fondazione Compagnia di San Paolo, Torino (2013.0922 to A. Boccaccio). S. Pifferi is a recipient of an EU Marie Curie Reintegration Grant (OLF-STOM n.334404).

The authors declare no competing financial interests.

Angus C. Nairn served as editor.
